Abstract

We study the problem of combinatorial pure exploration in the stochastic multi-armed bandit problem. We first construct a new measure of complexity that provably characterizes the learning performance of the algorithms we propose for the fixed confidence and the fixed budget setting. We show that this complexity is never higher than the one in existing work and illustrate a number of configurations in which it can be significantly smaller. While in general this improvement comes at the cost of increased computational complexity, we provide a series of examples, including a planning problem, where this extra cost is not significant.

1 Introduction

In the problem of best arm identification in the stochastic multi-armed bandit (MAB) setting (e.g., [Even-Dar et al., 2006], [Bubeck et al., 2009], [Audibert et al., 2010]), a learner has to identify the best arm/decision in a given decision space. At each step, the learner selects an action and receives a sample drawn from its corresponding reward distribution. Unlike in standard MAB, where the goal is to maximize the cumulative sum of rewards (e.g., [Robbins, 1952], [Auer et al., 2002]), here the performance is evaluated based on the value of the arm(s) returned at the end.

In the original form of the problem, the decision set is composed of a finite number of arms/decisions and the task is to identify the one with the highest expected value. This problem has been studied in two different settings. In the fixed confidence setting, the learner aims to minimize the number of pulls that allow her to identify the best arm with the desired confidence. In the fixed budget setting, the total number of pulls is fixed and the objective is to return the best arm with the highest confidence. In recent years, more complex forms of this problem have been studied. In [Kalyanakrishnan and Stone, 2010], [Kalyanakrishnan et al., 2012], [Gabillon et al., 2012], [Kaufmann and Kalyanakrishnan, 2013], the objective is to recommend the set of $m$ best arms. In [Gabillon et al., 2011], [Wang et al., 2013], a scenario in which the best arm must be identified within each of $m$ independent parallel bandit problems. In [Soare et al., 2014], the rewards of the arms depend linearly on an unknown parameter. Motivated by applications in project management and surveillance over a network of hospitals, [Ryzhov and Powell, 2011] moved to combinatorial decision sets and studied the scenario in which at each step the learner samples an edge of the graph and the goal is to find the path with the highest reward (i.e., the sum of the rewards of its edges). They assumed a Bayesian prior over the rewards of the arms and provided asymptotic results on the probability of error. [Chen et al., 2014] studied the same setting and proposed two novel algorithms for the fixed confidence and the fixed budget setting, called CLUCB and CSAR. They proved an upper bound on their performance that was complemented by a general lower bound on the problem setting. Finally, [Wu et al., 2015] studied the combinatorial case in which at each step the learner samples a path of the graph and the goal is to find the edge with the highest value. Finally, we note that the case of combinatorial actions/decisions has also been studied in the cumulative regret setting in [Cesa-Bianchi and Lugosi, 2012], [Chen et al., 2013], [Kveton et al., 2015].

In this paper, we follow the setting of [Chen et al., 2014] with the objective of designing algorithms with improved learning complexity relating the number of samples to the probability of error. That is, in the fixed confidence setting, the learning complexity is the required number of samples to achieve the desired confidence, while in the fixed budget setting it is the probability of error for a given budget.
of arm pulls available. We first introduce a new measure of complexity in Sect. 3. In Sect. 4 we propose algorithms for the fixed confidence and the fixed budget setting whose learning complexity depends on this new measure. Then in Sect. 5, we show that as our complexity measure is never larger than the one of Chen et al. [2014], this leads to improved learning complexity bounds. Finally in Sect. 6, we discuss the computational complexity of our algorithms and show that although they are computationally more expensive than those of Chen et al. [2014], this extra cost is not significant in several practical scenarios.

2 Problem Formulation

We consider a set $K$ of $|K|$ arms, where each arm $i \in K$ is characterized by a distribution $\nu_i \in [0, 1]$ with expected value $\mu_i$. The (combinatorial) decision space $C \subseteq 2^K$ contains decision sets (sets of arms) $U \subseteq K$, and the value of a decision set $U \in C$ is defined as $\mu_U = \sum_{i \in U} \mu_i$. In the following, we use upper-case letters $U$ to refer to decision sets. Without loss of generality we assume that for each arm $i \in K$, there exists at least one decision set $U \subseteq K$ such that $i \in U$ and at least one decision set $V \in C$ such that $i \notin V$. The gap between two decision sets is denoted by $\Delta_{U,V} = \mu_U - \mu_V$, and $U^* = \max_{U \in C} \mu_U$ is the best decision set with value $\mu^* = \mu_{U^*}$, which is assumed to be unique. We denote by $U \oplus V = (U \setminus V) \cup (V \setminus U)$ the exclusive disjunction between sets $U$ and $V$, i.e., the set of arms either in $U$ or in $V$, but not in both. Finally, the symmetric and asymmetric distances between two decision sets are defined as $d_{U,V} = |U \oplus V|$ and $d_{U,V} = |U \setminus V|$, respectively.

Following Chen et al. [2014], we characterize the decision space $C$ by a set of patches that can transform any decision set $U \in C$ to any other decision set $V \in C$, without leaving the decision space $C$.

Definition 1. An exchange set $b$ is an ordered pair of disjoint sets $b = (b_+, b_-)$ such that $b_+, b_- \subseteq K$ and $b_+ \cap b_- = \emptyset$. For any set $U$ and any exchange set $b = (b_+, b_-)$, we define $U \pm b = (U \setminus b_-) \cup b_+$ and $U \equiv b = (U \setminus b_+) \cup b_-$. The set $B$ is an exchange class for the decision space $C$ if for any pair of decision sets $U \neq V \in C$ and any arm $k \in \cup \setminus V$, there exists an exchange set $b = (b_+, b_-) \in B$ that satisfies the five constraints: (a) $k \in b_-$, (b) $b_+ \subseteq V \setminus U$, (c) $b_- \subseteq U \setminus V$, (d) $(U \pm b) \in C$, (e) $(V \equiv b) \in C$. The width of an exchange class is defined as $\text{width}(B) = \max_{(b_+, b_-) \in B} |b_+| + |b_-|$.

Definition 2. The decision set $U \in C$ is independent of the decision set $V \in C, U \neq V$, denoted by $U \perp V$, iff $b = (V \setminus U, U \setminus V)$ is the only non-empty exchange set that satisfies the constraints (b)-(e) of Definition 1 for the pair of decision sets $(U, V)$. It is easy to see that independence is symmetric, i.e., $U \perp V$ iff $V \perp U$.

The distributions $\{\nu_i\}_{i=1}^K$ are unknown to the learner. At each round $t$, the learner pulls an arm $I(t)$ and observes a sample drawn from $\nu_{I(t)}$, independent from the past. The learner estimates the mean of each arm $i$ by averaging the samples drawn from $\nu_i$ over time, i.e., $\hat{\mu}_i(t) = \frac{1}{n(t)} \sum_{s=1}^{n(t)} X_i(s)$, where $n(t)$ is the number of times that $i$ has been pulled by the end of round $t$ and $X_i(s)$ is the $s$-th sample observed from $\nu_i$. We denote by $\hat{\mu}_U(t) = \sum_{i \in U} \hat{\mu}_i(t)$ the empirical value of a decision set $U$, and by $\hat{U}^*(t) = \arg \max_{U \in C} \hat{\mu}_U(t)$ the best empirical decision set at round $t$.

In this paper, we consider both the fixed budget and the fixed confidence setting defined as follows.

In the fixed budget setting, the objective is return the best decision set with the largest possible confidence using a fixed budget of $n$ arm pulls. More formally, given a budget $n$, the performance of an algorithm is measured by the probability $\delta$ of not identifying the best decision set, i.e., $\tilde{\delta} = \Pr[\hat{U}^* \neq U^* \mid n]$. The smaller $\tilde{\delta}$, the better the algorithm is.

In the fixed confidence setting, the goal is to return the optimal decision set with fixed confidence after the smallest possible number of arm pulls. Given a confidence level $\delta$, if we denote by $\overline{n}$ the time when the algorithm stops, we want to have $\Pr[\hat{U}^* \neq U^* \mid \overline{n} \leq n] < \delta$. The performance of the algorithm is thus measured by the number of rounds $\overline{n}$, either in expectation or in high probability.

3 Definition of Learning Complexity

In this section, we introduce our novel complexity measure for combinatorial pure exploration problems. While in Section 4 we derive algorithms whose performance is actually characterized by this new measure of complexity, in the following we introduce it in a constructive way to provide a more solid intuition about its properties. In Section 7, we discuss its relationship to existing lower bounds and possible improvements.

Since the objective in combinatorial pure exploration is to identify the optimal set $U^* \in C$, we first focus on characterizing the complexity of discriminating between any two decision sets $U, V \in C$, i.e., determining whether $\mu_U > \mu_V$ or $\mu_U \leq \mu_V$. As usual, we expect that the smaller the gap $\Delta_{U,V}$, the harder it is to identify the better set. However in our setting, resources cannot be directly allocated to the sets, but rather need to be allocated to the arms in $U \cup V$ until the estimates of $\mu_U$ and $\mu_V$ are accurate enough to discriminate $U$ from $V$. In order to simplify the discussion, we focus on how often we have to pull arms $i \in U \cup V$ to identify the better set with confidence $1 - \delta$.

We consider an algorithm that sequentially selects arms in $U \cup V$ and
at the end of each step \( t \) constructs the empirical estimate \( \hat{\mu}_i(t) \) for each arm \( i \) using the \( T_i(t) \) samples of arm \( i \) that have been observed so far. By a direct application of Hoeffding’s inequality, we may construct confidence intervals

\[
|\hat{\mu}_i(t) - \mu_i| \leq \beta_i(t) = \sqrt{\frac{\log(4K/v^2)}{2T_i(t)}},
\]

which hold with probability at least \( 1 - \delta \) for all \( K' = \hat{\Delta}_{U,V} \) arms at any time step \( t > 0 \). At the end of step \( t \), we construct the empirical estimate of the gap between \( U \) and \( V \) as

\[
\hat{\Delta}_{V,U}(t) = \sum_{i \in V} \hat{\mu}_i(t) - \sum_{i \in U} \hat{\mu}_i(t) = \sum_{i \in V \setminus U} \hat{\mu}_i(t) - \sum_{j \in U \setminus V} \hat{\mu}_j(t),
\]

which shows that only arms in \( U \oplus V \) actually play a role in discriminating between \( U \) and \( V \). As a result, we consider a simple extension of the Hoeffding Races algorithm [Maron and Moore 1993], which selects arms in \( U \oplus V \) by using a round-robin strategy (in an arbitrary order) and stops at the first step \( t \) when the lower-bound on the gap is positive, i.e.,

\[
\hat{\Delta}_{V,U}(t) = \sum_{i \in U \oplus V} \beta_i(t) > 0.
\]

The sample complexity of such an algorithm is bounded in the following lemma.

**Lemma 1.** Let \( U, V \in \mathcal{C} \) such that \( \mu_V > \mu_U \) and let

\[
H_{U,V} = \hat{\Delta}_{U,V}^2/\Delta_{U,V}.\]

When the round-robin algorithm with the termination condition (2) stops after \( t \) steps, then for any arm \( i \in U \oplus V \), we have \( T_i(t) \leq 2H_{U,V} \log \left( \frac{4K^2}{\delta} \right) + 1 \) and \( V \) is returned as the better set with probability at least \( 1 - \delta \).

**Lemma 1** is obtained using classical techniques. The full proof is reported in Appendix E. Lemma 1 provides an upper bound on the number of times each arm in the disjunction \( U \oplus V \) should be pulled before learning that \( V \) is better than \( U \) with sufficiently high confidence. In particular, Lemma 1 shows that beyond the inverse dependency on the gap \( \Delta_{U,V} \), the upper bound also depends on the number of arms in the disjunction \( U \oplus V \). The number of arms \( \hat{\Delta}_{U,V} \) can be interpreted as a variance term, as the confidence interval associated to a set is proportional to \( \hat{\Delta}_{U,V} \). As a result, given a fixed gap \( \Delta \), it is easier to discriminate sets that differ by only few arms. This property implies that when trying to discard a suboptimal set \( \tilde{U} \) from \( \mathcal{C} \) (i.e., find that \( \tilde{U} \neq U^* \) with high confidence), it may be easier to compare \( U \) to a set \( \tilde{V} \neq U^* \) with \( \mu_V > \mu_U \) and smaller complexity \( H_{U,V} \). Thus, we introduce the following definition.

**Definition 4.** The complement of any decision set \( U \neq U^* \) is

\[
\mathcal{C}_U = \arg \min_{V \in \mathcal{C} : \mu_V > \mu_U} H_{U,V},
\]

where ties are broken in favor of \( V \) with smaller \( \hat{\Delta}_{U,V} \).

If \( H_{U,V} \) characterizes the complexity of discriminating between \( U \) and \( V \), \( \mathcal{C}_U \) is the set that is the most effective in revealing that \( U \) is actually suboptimal. The complement \( \mathcal{C}_U \) has also an additional important property.

**Lemma 2.** \( U \perp \mathcal{C}_U \) holds for all \( U \in \mathcal{C} \) with \( U \neq U^* \).

This lemma (proof in App. E), shows that for any suboptimal set \( U \) is independent from its complement \( \mathcal{C}_U \).

Lemma 1 suggests that in order to discard a suboptimal set \( U \), the most effective strategy is to pull all the arms in \( U \oplus \mathcal{C}_U \) a number of times proportional to \( H_{U,\mathcal{C}_U} \). Thus, we define the complexity of an arm as the largest complexity for discarding a set \( U \) with \( i \in U \oplus \mathcal{C}_U \).

**Definition 5.** The complexity of an arm \( i \in \mathcal{K} \) is

\[
H_i = \max_{U \in \mathcal{C} : i \in U \oplus \mathcal{C}_U} H_{U,\mathcal{C}_U}. \tag{4}
\]

As a direct consequence of Lemma 1 and Definition 5, we note that an algorithm pulling each arm proportionally to \( H_i \) and stopping when all sets but one are discarded returns an empirical best set \( \tilde{U}^* = \arg \max_{U \in \mathcal{C}} \hat{\mu}_U \) that is optimal with probability at least \( 1 - \delta \). Consequently, we define the global complexity \( H \) as the sum of the complexities of the individual arms in \( \mathcal{K} \).

**Definition 6.** The global complexity \( H \) is defined as

\[
H = \sum_{i \in \mathcal{K}} H_i. \tag{5}
\]

For notational convenience, we also introduce the notion of simplicity of a pair of decision sets \( (U, V) \) as

\[
G_{U,V} = \Delta_{U,V}/\hat{\Delta}_{U,V}. \tag{6}
\]

Unlike \( H_{U,V} \), \( G_{U,V} \) is an asymmetric quantity, i.e., \( G_{V,U} = -G_{U,V} \). We also define the simplicity of an arm \( i \in \mathcal{K} \) as \( G_i = \min_{U \in \mathcal{C}, i \in U \oplus \mathcal{C}_U} G_{U,\mathcal{C}_U} \). Note that simplicity is a positive quantity, i.e., \( G_{\mathcal{C}_U, U} > 0 \), since \( \mu_{\mathcal{C}_U} > \mu_U \). Also note that \( H_{U, V} = G_{U,V}^{-2} \) and \( H_i = G_i^{-2} \).

### 4 Learning Algorithms

In this section, we introduce novel learning algorithms for the fixed budget and the fixed confidence setting. Both algorithms are designed to discard an arm \( i \) whenever sufficient information is gathered to decide whether or not it belongs to \( U^* \). While for existing algorithms, this requires that the arms in \( U^* \) are pulled sufficiently often, our algorithms compare a decision set \( U \) not always to \( U^* \), but rather to \( \mathcal{C}_U \). Thus, they focus on pulling arms in both \( U \) and \( \mathcal{C}_U \) sufficiently often. This is achieved by computing

\[\text{See Appendix E for a proof that } H_i \text{ is well defined.}\]
Parameters: number of rounds $n$, set of arms $\mathcal{K}$, decision set $C$, and cumulative pulls scheme $n_0, n_1, \ldots, n_k$.

Let $K_i = K$, $k = 1$.

while $|K_k| \geq 1$ do
  Pull each arm $i \in K_k$ for $n_k = n_{k-1}$ rounds.
  Compute $\hat{U}^*_i(k) = \arg\max_{i \in \mathcal{K}_k} \hat{\mu}_i(k)$.
  Find $j_k = \max_{i \in \mathcal{K}_k} \hat{G}_i(k)$.
  Deactivate arm $j_k$, i.e., set $K_{k+1} = K_k \setminus j_k$.
  $k \leftarrow k + 1$
end while

Return $J_n = \arg\max_{i \in \mathcal{C}} \hat{\mu}_i(n)$

Figure 1: The fixed budget algorithm.

empirical estimates of the complexity measure $H_i$ and progressively discarding arms with low complexity. The resulting algorithms enjoy performance guarantees on probability of error and on sample complexity, where the bounds exhibit an explicit dependency on $H$. In Section 5 we show that this leads to a potential significant gain w.r.t. the algorithms of Chen et al. [2014]. The computational complexity of our algorithms is discussed in Section 6.

4.1 Fixed Budget

Figure 1 shows our fixed budget algorithm. Apart from the introduction of the new notion of complexity, $H_i$, the algorithm builds upon a rather standard rejection strategy shared by many existing algorithms such as Successive Rejects (SR) [Audibert et al., 2010], SAR [Wang et al., 2013], and CSAR [Chen et al., 2014], which is specifically designed for combinatorial problems. The algorithm runs over $K$ phases. At each phase $k$, it maintains a set of active arms $\mathcal{K}_k$ that are all pulled uniformly until they reach $n_k$ samples. At the end of a phase, we compute the empirical means $\hat{\mu}_i(k)$, the empirical gap for any pair of sets $U$ and $V$, as $\hat{G}_{U,V}(k) = \hat{\mu}_i(k) - \hat{\mu}_U(k)$, and the estimated optimal decision $\hat{U}^*(k) = \arg\max_{i \in \mathcal{C}_k} \hat{\mu}_i(k)$. Using these estimates, we also build empirical versions of the terms introduced in Section 3 such as the estimated simplicity between two sets $U$ and $V$ as $\hat{G}_{U,V}(k) = \hat{\Delta}_{U,V}(k) / \hat{\Delta}_{U,V}$, which in turn implies the following definitions for the empirical complement of a decision set $U \neq \hat{U}^*$,

$$\hat{C}_{U}(k) = \arg\max_{V \in C: \hat{\mu}_V(k) > \hat{\mu}_U(k)} \hat{G}_{V,U}(k),$$

and the estimated simplicity of an arm $i \in \mathcal{K}$,

$$\hat{G}_i(k) = \min_{U \in C: i \in \hat{C}_{U}(k)} \hat{G}_{i,U}(k).$$

In (6), ties are broken in favor of $V$ with the smaller distance $\hat{\Delta}_{U,V}$. At the end of each phase $k$, the easiest arm $j_k = \arg\max_{i \in \mathcal{K}_k} \hat{G}_i(k)$, i.e., the arm with largest estimated simplicity in $\mathcal{K}_k$, is removed from the active set. Note that $j_k$ is the arm for which it is easiest to determine whether it belongs to $U^*$ or not, and thus, if $j_k \in \hat{U}^*(k)$, then $j_k$ is accepted and will be a part of the final recommended solution $J_n$, otherwise it is rejected. In either case, it is not included in $\mathcal{K}_{k+1}$ and is not pulled anymore.

We use $n_k = \left\lceil \frac{n-K}{\log(K)} \right\rceil$, $k \in \mathcal{K}$, with $n_0 = 0$ and $\log(K) = \sum_{i=1}^{K} 1/i$. It is easy to verify that with this scheme the algorithm never exceeds the budget $n$. In fact, since at each of the $K$ phases one arm is deactivated, the total budget used is $n_{FB} = \sum_{k=1}^{K} n_k \leq K + \frac{K}{\log(K)} \left( \sum_{k=1}^{K} \frac{1}{k} \right) = n$. We prove the following performance guarantee for the algorithm.

**Theorem 1.** The probability of error of the fixed budget algorithm in Figure 1 is

$$\mathbb{P} \left[ \hat{U}^*(n) \neq U^* \right] \leq 2K^2 \exp \left( - \frac{n - K}{32\log(K) \overline{H}} \right),$$

where $\overline{H} = \max_{i \in \mathcal{K}} i \pi_i(1)$ and $\pi$ is a permutation of $K$ such that $\pi_1(1) \geq \pi_2(2) \geq \ldots \geq \pi_K(K)$. As noted in Audibert et al. [2010], it holds that $\overline{H} \leq H \leq \overline{H} \log(K)$.

The full proof that –like the algorithm– borrows ideas from Audibert et al. [2010], Wang et al. [2013], and Chen et al. [2014] can be found in Appendix C. Here we only provide a sketch proof. The proof proceeds by induction on the phases of the algorithm. The two induction hypotheses essentially claim that if an arm $i \notin \mathcal{K}_k$ has been deactivated during phase $l \in \{1, \ldots, k-1\}$, the number $n_l$ of samples obtained for arm $i$ is proportional to its complexity $H_i = 1 / G_i^2$, which is crucial for the correct functioning of the method. It first means that the deactivated arms have been pulled sufficiently often in order to determine whether they belong to the optimal set $U^*$. Moreover, although $j_k$ is selected among the active arms in $\mathcal{K}_k$ on the basis of the estimated simplicity, the computation of $\hat{G}_i$ requires comparing each set $U$ containing $i$ to its (estimated) complement $\hat{C}_U$ (see Definition 5). Since the arms in $\mathcal{C}_U$ may no longer be active, we need to guarantee that when they are deactivated, their values are estimated sufficiently precise, so that $\hat{C}_U$, and as a result $\hat{G}_i$, are accurate.

4.2 Fixed Confidence

Figure 2 shows our fixed confidence algorithm. At each step $t$, the algorithm first uses the samples up to step $t-1$ to compute an upper bound on the simplicity $\hat{G}_{U,V}(t)$ of any pair of decision sets $(U, V)$. To do so, we first define upper and lower bounds for the mean of an arm $i$ as $\hat{\mu}_i^+(t) = \hat{\mu}_i(t-1) + \beta_i(t-1)$ and $\hat{\mu}_i^-(t) = \hat{\mu}_i(t-1) - \beta_i(t-1)$, where $\beta_i(t-1)$ is the confidence interval for arm $i$ at time $t$ defined in (1). For any pair of decision sets $(U, V)$, we then compute an upper bound on their gap as $\hat{\Delta}_{U,V}^+(t) = \sum_{i \in U \setminus V} \hat{\mu}_i^+(t) - \sum_{j \in V \setminus U} \hat{\mu}_j^-(t)$ and on their simplicity as $\hat{G}_{U,V}^+(t) = \hat{\Delta}_{U,V}^+(t) / \hat{\Delta}_{U,V}^+$.\footnote{Note that the empty set can be considered a decision in $C$, which explains why $K$ and not $K-1$ phases are necessary. A default value then need to be associated with the empty set decision.}
At each step \(t\), the set \(U_t\) is constructed as the set of decision sets \(U\), whose upper bound on the gap is positive w.r.t. any other set \(V \in \mathcal{C}\). This corresponds to all sets that are still potential candidates for the best set \(U^*\) (i.e., there is not enough confidence to discard them). Then, the most uncertain arm belonging to the simplest pair \((U_t, V_t)\) is selected, and this is repeated until only one set in \(U_t\) is left, which is then returned as \(\hat{U}^*(t)\). While it would be natural to select the sets \((U_t, V_t)\) among those still “active” in \(U_t\), this would not guarantee a proper behavior for the algorithm. Similarly to the fixed budget case, the largest simplicity for a set \(U\) is associated to its complement \(V = \mathcal{C} \setminus U\), and thus, in order to guarantee that the upper bound on the estimated simplicity, \(\hat{G}_{U,V}^+(t)\), is accurate, we need to guarantee that all the arms in \(V\) have been pulled at least a number of times proportional to their complexity. This is achieved by introducing an additional set \(U'_t\). While in constructing \(U'_t\), a set \(U\) is dropped when it is dominated with high confidence, i.e., the upper bound on its gap \(\Delta_{U,V}^+(t)\) is negative for at least one set \(V\). \(U'_t\) is more conservative and requires the gap to be negative by “enough” margin before actually discarding a set. That is, we introduce the threshold \(T_{U,V}(t) > 0\), and let a set \(U\) be discarded from \(U'_t\) only if there is a set \(V\) such that \(\Delta_{U,V}^+(t) < -T_{U,V}(t)\). This allows us to guarantee that all the arms that could be involved in identifying a suboptimal set are pulled often enough. In fact, after computing \(U'_t\), the algorithm identifies the pair of decision sets \((U_t, V_t)\) with the highest upper bound on simplicity in \(U'_t\) and selects among \((U_t, V_t)\) the decision \(W\) with the largest sum of uncertainty terms \(\beta_i(t - 1)\) for \(i \in W\). Then the algorithm pulls the arm with the largest uncertainty in \(W \cap (U_t \cup V_t)\).

We now state the sample complexity of the algorithm.

**Theorem 2.** The algorithm in Figure 2 stops after \(\tilde{n} = O(H \log(\frac{HK}{\delta}))\) steps and returns the optimal decision set \(U^*\) with probability at least \(1 - \delta\).

We report the proof in Appendix A. For all \(t\), we define \(\hat{G}^+(t) = \max_{U \in U'_t, V \in \mathcal{C}} \hat{G}^+_{U,V}(t)\). The main idea is to show that \(\hat{G}^+(t)\) is upper bounded by \(\beta_{\tilde{U}(t)}\) (Lemma 1) and lower bounded by \(G_i(t)\) (Lemma 5), thus obtaining that \(G_i(t) \leq \hat{G}^+(t) \leq \beta_{\tilde{U}(t)}\). Given the definition of \(\beta\) in (1), we recover an upper bound on the number of pulls \(T_{U}(t)\) for each arm, and thus, bound the overall sample complexity.

## 5 Comparison of Learning Complexities

In this section we show that the interest in designing algorithms whose performance is characterized by the complexity measure of Definition 5 resides on the fact that this represents a significant improvement w.r.t. previous pure exploration combinatorial algorithms. We first show that the complexity \(H_i\) is never higher than the complexity measure \(H_i^\circ\) introduced by Chen et al. [2014] for the performance analysis of the algorithms CLUCB and CSAR. Then we provide illustrative examples showing that our new complexity measure can be significantly smaller.

We recall the definition of the complexity measure of Chen et al. [2014]. For any arm \(i \in K\), the gap is defined as

\[
\Delta_i^\circ = \begin{cases}
\mu_i - \max_{U \in K, i \notin U} \mu_U & \text{if } i \notin U^*, \\
\mu_i - \max_{U \in K, i \in U} \mu_U & \text{if } i \in U^*.
\end{cases}
\]

The width of \(\mathcal{C}\) is the width of the smallest exchange class for \(\mathcal{C}\), that is \(\text{width}(\mathcal{C}) = \min \text{width}(\mathcal{B})\). The following theorem shows that for any arm \(i \in K\) our complexity measure \(H_i\) is never higher than the measure \(H_i^\circ\) of Chen et al. [2014].

**Theorem 3.** For all \(i \in K\), \(H_i^\circ \geq H_i\).

We first provide some intuition about the statement of the theorem. The complexity \(H_i\) of an arm \(i\) is defined as the maximum over the complexities of the decision sets \(U\) for which \(i \in U \cup \mathcal{C}_i\). On the other hand, \(H_i^\circ\) only considers the maximum over the sets \(U\) with \(i \in U\). We therefore need to guarantee that the extra terms in the maximum of our definition do not lead to a larger value compared to \(H_i^\circ\). Consider for instance the specific case \(\mathcal{C} = \{U, V, U^*\} + V = \mathcal{C}_i\) and \(V\) being the only decision set containing \(i\). Then \(U^* = C_i\), \(H_i^\circ = H_i^\circ\), and \(H_i = \max\{H_{V,C_i}, H_{U, V}\}\), so that if \(H_{U, V} > H_{V, C_i}\) then \(H_i > H_i^\circ\). Fortunately, we can show in Appendix C and D that generally \(H_{V, C_i} \geq H_{U, V}\), so that the additional terms in the maximum do not increase the value of \(H_i\). More

Notice that in the original paper, the complexity of an arm is defined as \((1/\Delta_i^\circ)^2\), but looking at the statements of the theorems, the complexity of \(i\) is always multiplied by the square of the width of the decision space.
Figure 3: Examples of decision spaces where $H$ is significantly smaller than $H_i^\circ$. Each arm is identified with an edge of a graph, and $C$ corresponds to the possible paths (without loops) from the source $S$ to the target $T$.

generally, we prove that for all $i \not\in U^*$, the maximum in the complexity $H_i$ is attained by a set $U$ such that $i \in U \setminus C_U$.

Now we proceed with a proof sketch. Thus, consider an arm $i \not\in U^*$ and let

$$U_i^\circ = \arg \max_{U \in C} \mu_U, \quad U_i = \arg \max_{U \in C \subset U \supseteq C_U} H_{U_i,C_U}.$$ Notice that $U_i^\circ$ is the decision set that implicitly defines the complexity of arm $i$ according to the definition of $\Delta_i^\circ$. As mentioned before, $i \in U_i$. Let $V_i = C_{U_i}$, where $C^*$ is a variation of $C$ such that if we define an exchange set $b$ with $b_+ = V_i \setminus U_i$ and $b_- = U_i \setminus V_i$, we have that $V_i$ is indeed “between” $U$ and $U^*$, i.e., requiring $U^* \not\subseteq b \in C$ and $i \in b_-$. As a result, we have that $\Delta_{U^*,U^*} = \min_{U \in C \subseteq U \supseteq C_U} \Delta_{U^*,U^*} \leq H_{U^*,U^*} \leq \Delta_{U^*,U} = \Delta_{\hat{C}_{U^*},U} = \sum_{j \in K} H_j^\circ$, since $i$ belongs to $b_-$. Furthermore, recalling Definition 3 of independent sets, we notice that an equivalent interpretation of the width of $C$ is to consider it as the maximal distance $\hat{d}_{U,V}$ between any two independent sets $U,V$ (i.e., $U \perp V$). In fact, $\hat{d}_{U,V}$ counts the number of arms in the disjunction $U \vee V$.

Therefore, in the case of independent sets, this coincides with an exchange set $b$ with $b_+ = V_i \setminus U_i$ and $b_- = U_i \setminus V_i$ such that $\hat{d}_{U_i,V} = |b_+| + |b_-|$. Since by Lemma 2 $U_i$ is independent from its complement $V_i$, we have $\text{width}(C) \geq \hat{d}_{U_i,V_i}$. Summarizing, we obtain the claimed

$$H_i^\circ = \text{width}(C)^2/\Delta_i^2 \geq \hat{d}_{U_i,V_i}^2/\Delta_i^2, H_i = H_i.$$ The most interesting aspect of this result is that the potential improvement of $H_i$ over $H_i^\circ$ may be achieved on both terms characterizing the complexity, that is, the distance $\hat{d}_{U_i,V_i}$ (which can be smaller than the width of $C$) and the gap $\Delta_{U_i,V_i}$ (which can be larger than the gap between $U_i$ and $U^*$). This is demonstrated in the two following illustrative examples, in which $H_i$ is indeed much smaller than $H_i^\circ$.

Example 1: Comparing $U$ to $C_U$ instead of $U^*$. The definition of $\Delta_i^\circ$ always depends on the comparison of sets $U$ containing $i$ to the optimal decision set $U^*$. The following example demonstrates that comparing decision sets to their complement can considerably reduce the overall complexity of an arm $i$. Consider the shortest path problem with $K = \{1, \ldots, m, a, b, i\}$ illustrated in Figure 3(a).

The optimal path between source node $S$ and exit node $T$ is the green path $U^* = \{a\}$ with $\mu^* = 1$. We first focus on the complexity of the red arm $i$. This arm only belongs to the decision set $U = \{i, 1, \ldots, m\}$ (i.e., the black and red path).

The complexity of discriminating $U$ from $U^*$ is $H_{U^*,U} = \sum_{j \in K} H_j^\circ = (m+2)^2 = (m+2)^2$. Notice that $H_{U^*,U}$ coincides with $H_i^\circ$ since the largest exchange set in this problem is indeed the one transforming $U$ into $U^*$, and thus $H_i^\circ = \text{width}(C)^2/\Delta_i^2 = (m+2)^2$. On the other hand, the complexity of discriminating $U$ from the set $V = \{b, 1, \ldots, m\}$, which differs from $U$ only by the exchange set $(\{i\}, \{b\})$, corresponds to $H_{V,U} = \hat{d}_{U,V}^2 = \frac{2^2}{m^2}$. As a result, as soon as $m > 2\epsilon/(1-\epsilon)$, we have $H_i = H_{V,U} < H_{U^*,U} = H_i^\circ$. In particular, $H_i^\circ = (1-\epsilon)^2(2^2m^2)H_i$. Since we can take $\epsilon$ arbitrarily small while $m$ is of order of $K$, we have $H_i^\circ = O(K^2)H_i$, implying that complexity $H_i$ can be $K^2$ times smaller than the complexity proposed by [Chen et al., 2014]. While this shows already the potential of the complexity measure $H_i$, it is limited to one single arm, and it does not immediately show that the overall complexity of finding the optimal set is significantly reduced. However, it is enough to slightly modify the previous example by adding $p$ copies of arm $i$, thus leading to a total number of $K = m + 2 + p$ arms. Choosing $\epsilon = 1/2$ we have $H = \sum_{j \in K} H_j = \sum_{j=1}^{m+2} H_j + pH_i = 4(m+2)^3 + 16p$.

Example 2: Width of the graph vs individual pair distance. Unlike in the definition of $H_i^\circ$, where the distance between sets only appears in form of the width of the global decision set $C$, $H_i$ takes into consideration the specific distances $\hat{d}_{U_i,C_U}$ for each $U$ with $i \in U$. Since $\text{width}(C)$ may be larger than $\hat{d}_{U_i,C_U}$, we expect $H_i$ to better adapt to the “local” geometry of $C$. We illustrate this intuition in the example shown in Figure 3(b). This is a shortest path problem in a graph between a source node $S$ and an exit node $T$, where $K = \{1, \ldots, m, a, i\}$ and the optimal path is $U^* = \{a, 1, \ldots, m/2\}$ (i.e., the blue edge followed by the top path). We focus on the complexity of the red arm $i$. Let $V = \{i, 1, \ldots, m/2\}$ (i.e., the red edge followed by the top path) be the best path containing $i$. Then $\Delta_i^\circ = \Delta_{U^*,V} = \frac{1}{m}$. The width of the decision space is

---

\[4\] Actually, the goal is to maximize the rewards over the edges in a path.

\[5\] Again, we actually want to maximize rewards over the path.
The complexity of finding the best estimated decision is exponential in the number of arms (e.g., maximum matching). While in general, the computational complexity cannot be improved w.r.t.

In this problem, the learning complexity cannot be improved w.r.t.

Nonetheless, we can exploit the structure of the problem to match their computational complexity. We first notice that any two independent sets $U$ and $V$ always differ by only one arm. In fact, if they differ by more than one arm, then there always exists more than one way to bring $U$ closer to $V$ by a one-arm transformation and at the same time stay in $C$. As a result, when computing $H_i$, we can directly compare $i$ with all the arms in the same bandit. For instance, in Fig. 4(a) computing $H_1$ would normally require looping over each decision set $U$ including arm 1 and considering all the other decisions to identify its complement. Let us consider $U = \{1, 3, 5\}$, then its complement is $C_U = \{2, 3, 5\}$, which only differs by arm 2. This is the same for all $U$ containing 1 and thus, when computing $H_1$ we can simply compare it to arm 2 without actually looping over all the decision sets.

As a result, computing the learning complexity reduces to comparing arms within the same bandit, thus leading to $M$ independent problems and a complexity of $O(K)$. $K \approx |C|$, the tree-planning case: Whenever $|C|$ is of the same order as $K$, then the computational complexity is tractable. This means that, for instance, in the illustrative examples discussed in Sect. 5 we not only enjoy a significantly smaller learning complexity (e.g., with a reduction of order $O(K^2)$) but we also match the computational complexity of the methods proposed by [Chen et al., 2014]. An even more interesting case is the problem of planning. In this case, $C$ describes a tree structure of depth $m$ and each node has the same branching factor $a$. An arm $i$ is an edge of the tree with associated weight $\mu_i$, and a decision set $U$ is a path from the root to a leaf. The objective is to find a decision set (i.e., a path) that maximizes the sum of its weights. This setting corresponds to the open-loop planning problem of maximizing the expected sum of rewards over $m$ consecutive actions (chosen in a set of $a$ actions) from a starting state when the state dynamics is deterministic and the reward distributions are unknown. This type of problem has been previously studied with discounted rewards [Bubeck and Munos, 2010; Munos, 2014].

In this problem, $2|C| \approx K$ as the number of decisions (paths) is equal to the number of leaves in the tree. While this already shows that our computational complexity is
comparable to previous methods, in the following we push the comparison even further. In the fixed budget setting, the CSAR algorithm [Chen et al., 2014] needs to query a shortest path oracle for each edge $i$ to determine the paths with largest value including and not including arm $i$. This procedure, if implemented naively, leads to an overall complexity of order $O(K^2)$ for each arm the computation requires $O(K \log(K))$ operations using a simplified version of Dijkstra), which matches our $O(|\mathcal{C}|^2)$ complexity. We conjecture that this computational complexity can be actually reduced to $Km$ for both our and their algorithm. We focus on our algorithms and highlight a technique that can be used to reduce the computational complexity in general. First, using the Dijkstra algorithm gives the best path from any node to the corresponding leaves. Our algorithms will then compute $H_{U,C,U}$ for all $U$. However, the set of decisions (paths) $V \neq U$ can be clustered into $m$ groups of sets depending on the first node where they differ from $U$ among the $m$ possible ones. Since the distance $d_{U,V}$ is constant within these clusters, identifying the complement $\arg \min H_{U,V}$ within each cluster corresponds to finding the set $V$ with the largest value, which has already been computed by the Dijkstra algorithm. So for each $U$ we need to consider $m$ clusters, which would permit to reduce the overall complexity to $Km$. This complexity is of the same order as for the CLUCB fixed confidence algorithm [Chen et al., 2014] where just one call to the Dijkstra algorithm is needed.

Not only in this setting our algorithms can be implemented efficiently, but we can also show an example where the learning complexity is significantly improved over [Chen et al., 2014]. Let us consider the tree in Figure 4(b) if $\mu_i = .9$ for all edges except the leaf edges with odd numbers 5, 7, 11, 13 for which $\mu_i = 0$ and $\mu_4 = 1$. In this case, arms 5, 7, 11, 13 belong to only one decision set $U$ each and thus computing their complexity coincides with finding the complement $C_U$ and computing $H_{U,C,U}$. Since almost all paths have the same value, the $C_U$ is chosen as the set $V$ minimizing $d_{U,V}$, which is simply the path differing from $U$ for only the last edge, i.e., $d_{U,V} = 1$. Comparing to $H_i^C$, which has width($C$) = $m$, for all such arms we have $mH_i = O(H_i^C)$. Since the proportion of this type of arms grows with the branching factor $a$, this improvement can reduce the global complexity $H$ by a factor $m$.

7 Discussion

We have seen in Section 5 that using the complexity measure $H$ one can obtain improved results on the learning complexity. This naturally raises the question whether the obtained upper bounds for our algorithms are optimal. The core of the definition of $H_i$ is indeed the complexity $H_{U,V}$ of discriminating between any two decision sets $U$ and $V$. While in Section 3 we gave a constructive definition, Chen et al. [2014] provide a lower bound on the “cumulative” number of samples for each exchange set. In particular, they show that for any arm $j \in \mathcal{K}$, there exists an exchange set $b = (b_+, b_-)$ such that $j \in b_+ \cup b_-$ and

$$\mathbb{E} \left[ \sum_{i \in b_+ \cup b_-} T_i(t) \right] \geq \frac{(|b_+| + |b_-|)^2}{2 \Delta_j^2} \log(1/4\delta), \hspace{1cm} (8)$$

where $t$ is the stopping time at which the optimal set is returned w.p. $1 - \delta$. As a result, a proper lower bound in the fixed confidence setting is derived from the optimization problem $\min_{E[T_i(t)] \in B} \sum_{i \in \mathcal{K}} \mathbb{E}[T_i(t)] \log(1/4\delta)$, subject to the constraints of the form in (8), for all exchange sets $b \in B$ and arms $j \in b_+ \cup b_-$. While it is difficult to have a clear understanding of the resulting overall sample complexity for the lower bound, we can greatly simplify it by considering the simple case of $C = \{U, U^*\}$, for which $b = (U^* \setminus U, U^* \setminus U^*)$, and an algorithm that pulls all the arms in $b_+ \cup b_-$ uniformly. Then, for each arm $i \in U \oplus U^*$, the lower bound of equation (8) becomes

$$\mathbb{E}[T_i(t)] \geq \frac{|b_+| + |b_-|}{2 \Delta_{U \oplus U^*}} \log(1/4\delta), \hspace{1cm} (9)$$

which strongly resembles our definition of $H_{U \oplus U^*}$. We first notice that the major gap is related to the fact that in $H_{U \oplus U^*}$ the numerator has the distance squared. We conjecture that this gap could be filled by using more accurate deviation inequalities in bounding $|\mu_U - \mu_U|$ so that the confidence bound has the sum inside the square root. On the other hand, the major gap resides on the fact that equation (9) considers a simple uniform allocation over arms in the disjunction, while the full lower bound in equation (8) allows for more sophisticated allocation strategies and considers the interplay between the constraints imposed by the exchange sets in $B$. Quantifying the resulting gap and determining whether it can be actually filled remains an open question. A first step may be to ask whether the complexity could be defined using the asymmetric distance $d_{U,V}$ between two sets $U, V$, instead of $d_{U,V}$. Notice that, as this distance plays a similar role here as the variance $\sigma_i^2$ of an arm $i$ in the standard single-bandit best arm identification problem, it is already an open question to see whether in the fixed budget setting the complexity of an arm $i$ is $\sigma_i^2 / \Delta_i^2$ instead of the standard $\left(\sigma_i^2 + \sigma_{i^*}^2\right) / \Delta_i^2$, where $i^*$ is the best arm.

References

A Proof of Lemma 1

Proof. Let $\bar{t}$ be the first time when the condition in equation (2) is met, then at time $\bar{t} - 1$ we have that

$$\hat{\Delta}_{V,U}(\bar{t} - 1) - \sum_{i \in U \oplus V} \beta_i(\bar{t} - 1) \leq 0,$$

which implies that

$$\Delta_{V,U} - 2 \sum_{i \in U \oplus V} \beta_i(\bar{t} - 1) \leq 0,$$

and thus

$$\sum_{i \in U \oplus V} \sqrt{\frac{\log 4K'(t-1)^2}{\delta}} \geq \frac{\Delta_{V,U}}{2}.$$

Since the algorithm is selecting arms in $U \oplus V$ using a round-robin strategy, at any time $T_i(t) = T_j(t) \pm 1$ for any pair of arms $i, j$. Thus, let $j$ be the least pulled arm at round $\bar{t} - 1$ (i.e., $j \in \arg \min T_i(\bar{t} - 1)$), then the previous inequality can be written as

$$\Delta_{U,V} \sqrt{\frac{\log 4K'(t-1)^2}{\delta}} \geq \frac{\Delta_{V,U}}{2},$$

which leads to the statement. \qed

B The Complexity in Equation (4) is Well-defined

In order to prove that our complexity measure in equation (4) is well-defined, we have to show that the $\max$ operator actually returns a value, that is, that there exists at least one element in the argument of the $\max$ operator. This is done in the following proposition.

Proposition 1. Let $Q_i$ be the set of the decision sets in the argument of the $\max$ operator in equation (4), i.e.,

$$Q_i = \{U \in C : i \in U \oplus C_U\}.$$

Then $Q_i \neq \emptyset$ for all $i$ in $K$.

Proof. We distinguish the following two cases:

Case 1) $i \notin U^*$

According to the assumption made in Section 2 there exists a decision set $V \in C$ such that $i \in V$. Note that $i$ does not necessarily belong to $V \oplus C_V$. We construct a sequence of decision sets $X = \{X_1, \ldots, X_p\}$ such that $X_1 = V$, for all $j \in \{1, \ldots, p - 1\}, i \in X_j$ and $X_{j+1} = C_{X_j}$, and $i \notin X_p$. As a result, setting $U = X_{p-1}$ and $C_U = X_p$, we have that $i \in U \oplus C_U$, and thus, $Q_i \neq \emptyset$.

Case 2) $i \in U^*$

Let $V = \arg \max_{U \in C : i \notin U} \mu_U$. Then $C_V$ exists, because $i \in U^*$. Moreover $i \in C_V$, as otherwise we obtain the contradiction $\mu_{C_V} > \mu_V = \max_{U \in C : i \notin U} \mu_U \geq \mu_{C_V}$. Therefore, $i \in C_V \setminus V$, so that $V \in Q_i$ and $Q_i \neq \emptyset$. \qed

Note that $X$ is not only finite but also contains a decision set $X_p$, such that $i \notin X_p$. The first claim comes from the definition of complement that gives us $\mu_{X_{j+1}} > \mu_{X_j}$, $\forall j \in \{1, \ldots, p - 1\}$, and the fact that $C$ is finite. For the second claim note that as $i \notin U^*$, $X$ has at least two elements.
C Useful Properties of the Complexity $H_{U,V}$

In this appendix, we prove several useful properties of the complexity $H_{U,V}$ later, particularly in the proof that our complexity measure is not higher than the measure used by Chen et al. [2014].

The first proposition shows that the distance $\overline{d}_{U,V}$ between two decision sets $U$ and $V$ follows a triangle inequality.

**Proposition 2.** For any three distinct decision sets $U, V, W \in C$, we have, $U \oplus V \subseteq (U \oplus W) \cup (W \oplus V)$ and $\overline{d}_{U,V} \leq \overline{d}_{U,W} + \overline{d}_{W,V}$. Moreover, if $(U \oplus W) \cap (W \oplus V) = \emptyset$ then $U \oplus V = (U \oplus W) \cup (W \oplus V)$ and $\overline{d}_{U,V} = \overline{d}_{U,W} + \overline{d}_{W,V}$.

**Proof.** To prove the statements for $U \oplus V$, we first prove that

$$U \setminus V = \left(\left(U \setminus V\right) \cup \left(U \setminus V \cap W\right)\right) \cup \left((W \setminus V) \setminus (W \setminus U)\right) \subseteq (U \setminus W) \cup (W \setminus V). \tag{11}$$

Taking the union of (11) and (12) gives

$$V \setminus U \subseteq (V \setminus W) \cup (W \setminus U). \tag{13}$$

and as a result

$$\overline{d}_{U,V} \leq \overline{d}_{U,W} + \overline{d}_{W,V}. \tag{19}$$

The second claim is straightforward from (14) and the definition of symmetric distance $\overline{d}$, i.e., $\overline{d}_{U,V} = \overline{d}_{U,W} + \overline{d}_{W,V}$.

To prove the second part of the proposition, we start from (11), that is,

$$U \setminus V = \left(\left(U \setminus V\right) \cup \left(U \setminus V \cap W\right)\right) \cup \left((W \setminus V) \setminus (W \setminus U)\right),$$

from which by our assumption $(U \oplus W) \cap (W \oplus V) = \emptyset$ we obtain

$$A \cup B = (X \cup S) \cap (X \cup Z) \cap (Y \cup S) \cap (Y \cup Z) = \emptyset \Rightarrow A = \emptyset \text{ and } B = \emptyset. \tag{15}$$

From (15), (C) may be written as

$$U \setminus V = (U \setminus W) \cup (W \setminus V). \tag{16}$$

Similarly, one can show that

$$V \setminus U = (V \setminus W) \cup (W \setminus U). \tag{17}$$

Taking union from both sides of (16) and (17), we obtain

$$U \oplus V = (U \oplus W) \cup (W \oplus V),$$

and as a result $\overline{d}_{U,V} = \overline{d}_{U,W} + \overline{d}_{W,V}$, which completes the proof of the second part of the proposition.

The next proposition proves useful properties for the complexity of two decision sets.

**Proposition 3.** For any three decision sets $U, V, W \in C$ with $\mu_U < \mu_V < \mu_W$, we have

$$H_{U,W} \leq \max(H_{U,V}, H_{V,W}). \tag{18}$$

Furthermore, if $(U \oplus V) \cap (V \oplus W) = \emptyset$, then

$$H_{U,W} \geq \min(H_{U,V}, H_{V,W}), \tag{19}$$

and finally, the above two inequalities are strict if $H_{U,V} \neq H_{V,W}$.
Proof. We write
\[ \Delta_{W,U} = \mu_W - \mu_U = \mu_W - \mu_U + \mu_V - \mu_U = \Delta_{W,V} + \Delta_{V,U}. \] (20)

By assumption, we have \( \mu_W > \mu_V \) and \( \mu_V > \mu_U \), and thus, \( \Delta_{W,V} > 0 \) and \( \Delta_{V,U} > 0 \). As a result, we may write
\[ \frac{\partial_{U,W}}{\Delta_{W,U}} \overset{(a)}{\leq} \frac{\partial_{U,V} + \partial_{V,W}}{\Delta_{W,V} + \Delta_{V,U}} \overset{(b)}{\leq} \max\left(\frac{\partial_{U,V}}{\Delta_{V,U}}, \frac{\partial_{V,W}}{\Delta_{W,V}}\right), \] (21)

where (a) follows from Proposition 2 and (20), and (b) follows from the fact that for any positive \( a, b, c, d \geq 0 \), it holds that \( \frac{a+b}{c+d} \leq \min\left(\frac{a}{c}, \frac{b}{d}\right) \). From (21), we get
\[ \frac{\partial_{U,W}}{\Delta_{W,U}} \leq \max\left(\frac{\partial_{U,V}}{\Delta_{V,U}}, \frac{\partial_{V,W}}{\Delta_{W,V}}\right), \]
which gives us (18).

The second statement is similarly proved as
\[ \frac{\partial_{U,W}}{\Delta_{W,U}} \overset{(a)}{=} \frac{\partial_{U,V} + \partial_{V,W}}{\Delta_{W,V} + \Delta_{V,U}} \overset{(b)}{=} \min\left(\frac{\partial_{U,V}}{\Delta_{V,U}}, \frac{\partial_{V,W}}{\Delta_{W,V}}\right), \] (22)

where (a) is true under the assumption that \( (V \cup U) \cap (V \cup W) = \emptyset \) from Proposition 2, and (b) follows from the fact that for any positive \( a, b, c, d \geq 0 \), it holds that \( \min\left(\frac{a}{c}, \frac{b}{d}\right) \leq \frac{a+b}{c+d} \). From (22) it follows that
\[ \frac{\partial_{U,W}}{\Delta_{W,U}} \geq \min\left(\frac{\partial_{U,V}}{\Delta_{V,U}}, \frac{\partial_{V,W}}{\Delta_{W,V}}\right), \]
which gives us (19).

The proof of the very last statement, the strict inequalities, comes directly from the fact that when \( \frac{a}{c} \neq \frac{b}{d} \), the two inequalities at step (b) of (21) and (22) become strict. \[ \square \]

In the last proposition of this section, we show that the complexity of discriminating between a decision set \( U \neq U^* \) and its complement \( V = C_U \) is less than the complexity of discriminating between \( V = C_U \) and its complement \( W = C_V = C_{C_U} \), provided that the complement of \( U \) is not the best decision set \( U^* \), i.e., \( V = C_U \neq U^* \).

**Proposition 4.** For any decision set \( U \neq U^* \) with \( V = C_U \neq U^* \) and \( W = C_V = C_{C_U} \), it holds that \( H_{U,V} \leq H_{V,W} \).

Proof. We prove the statement by contradiction. Let us assume that \( H_{U,V} > H_{V,W} \). Since \( V \neq U^* \) and by definition of complement, we have \( \mu_V < \mu_U < \mu_W \). As a result, \( H_{U,W} \leq H_{U,V} \leq H_{V,W} \) from Proposition 3. Note that this inequality is strict, whenever \( H_{U,V} \neq H_{V,W} \), again according to Proposition 3, and since we assumed that \( H_{U,V} > H_{V,W} \), we have \( H_{U,W} < H_{U,V} \). This gives us
\[ H_{U,V} = H_{U,C_U} = \min_{Z \in C_U: \mu_Z > \mu_U} H_{U,Z} \leq H_{U,W} < H_{U,V}, \]
which leads to the contradiction that \( H_{U,V} < H_{U,V} \). \[ \square \]

## D Equivalence of the Different Notions of Arm Complexity

In this section, we give two alternative notions of complexity of an arm that are equivalent to the original definition \( H_i \) of equation [4]. In the analysis of the algorithms (see Appendices G and H) we will use the definition of the complexity that is the most handy. The equivalence proof requires the results of Appendix C, especially Proposition 4. We start with the definition of the alternative complexity notions and two intermediate results that will be needed for the equivalence proof given at the end of this section.

---

9Here is the proof: Assume without loss of generality that \( \frac{a}{c} \leq \frac{b}{d} \). Then \( \frac{a+b}{c+d} \leq \frac{bc/(c+d)}{bd/(c+d)} = \frac{b}{d} = \max\left(\frac{a}{c}, \frac{b}{d}\right) \).

10The proof is analogous to the previous footnote: Assume without loss of generality that \( \frac{a}{c} \leq \frac{b}{d} \). Then \( \frac{a+b}{c+d} \geq \frac{a+bc}{ca+bd} = \frac{a(d+c+1)}{ca+bd} = \frac{a}{c} = \min\left(\frac{a}{c}, \frac{b}{d}\right) \).
Definition 7. Our two notions of complexity for an arm \( i \in \mathcal{K} \), \( \mathcal{H}^1 \) and \( \mathcal{H}^2 \), are defined as

\[
\mathcal{H}_i^1 = \begin{cases} 
\max_{U \in C: i \notin C_U} H_{U,C_U} & \text{if } i \notin U^*, \\
\max_{U \in C: i \in C_U \setminus U} H_{U,C_U} & \text{if } i \in U^*. 
\end{cases} \\
\mathcal{H}_i^2 = \begin{cases} 
\max_{U \in C: i \notin C_U} H_{U,C_U} & \text{if } i \notin U^*, \\
\max_{U \in C: i \notin C_U} H_{U,C_U} & \text{if } i \in U^*. 
\end{cases}
\]

The following proposition plays an important role in proving the equivalence \( \mathcal{H}_i^1 = H_i, \forall i \in \mathcal{K} \). It shows that if \( i \in (U \oplus C_U) \), then \( \mathcal{H}_i^1 \geq H_{U,C_U} \).

**Proposition 5.** For any decision set \( U \in \mathcal{C} \) such that \( U \neq U^* \), and any arm \( i \in (U \oplus C_U) \), we have \( \mathcal{H}_i^1 \geq H_{U,C_U} \).

**Proof.** We consider the following two cases for a fixed arm \( i \in (U \oplus C_U) \):

**Case 1)** \( i \in U^* \)

If \( i \in C_U \setminus U \), the result follows directly from the definition of \( \mathcal{H}_i^1 \). If \( i \in U \setminus C_U \), similar to the proof of Proposition 1 in Appendix B, we construct a sequence of decision sets \( \{X_1, \ldots, X_p\} \) such that \( X_1 = U \), for all \( j \in \{2, \ldots, p-1\}, i \notin X_j \) and \( X_{j+1} = C_{X_j} \), and \( i \in X_p \). Note that \( \{X_2, \ldots, X_p\} \) is a sequence of decision sets and their complements that do not contain arm \( i \) until a set \( X_p \) is generated that contains \( i \). From Proposition 4, we have that \( H_{X_j, X_{j+1}} \geq H_{X_{j-1}, X_j}, \forall j \in \{2, \ldots, p-1\} \). Now starting from the definition of \( \mathcal{H}_i^1 \), we may write

\[
\mathcal{H}_i^1 = \max_{Z: C_Z \neq Z} H_{Z, C_Z} \geq H_{X_{p-1}, X_p} \geq H_{X_1, X_2} = H_{U, C_U},
\]

which proves the claim of the proposition. Note that (a) comes from the fact that \( i \in C_{X_{p-1}} \setminus X_{p-1} \) by definition of the sequence.

**Case 2)** \( i \notin U^* \)

If \( i \in C_U \setminus U \), the result follows directly from the definition of \( \mathcal{H}_i^1 \). When \( i \in U \setminus C_U \), we construct a sequence of decision sets \( \{X_1, \ldots, X_p\} \) such that \( X_1 = U \), for all \( j \in \{2, \ldots, p-1\}, i \notin X_j \) and \( X_{j+1} = C_{X_j} \), and \( i \notin X_p \). This is a sequence of decision sets and their complements that contain arm \( i \) until a set \( X_p \) is generated that does not contain \( i \). As a result \( i \in X_{p-1} \setminus C_{X_{p-1}} \). From Proposition 4, we have that \( H_{X_j, X_{j+1}} \geq H_{X_{j-1}, X_j}, \forall j \in \{2, \ldots, p-1\} \). Now starting from the definition of \( \mathcal{H}_i^1 \), we may write

\[
\mathcal{H}_i^1 = \max_{Z: C_Z \neq Z} H_{Z, C_Z} \geq H_{X_{p-1}, X_p} \geq H_{X_1, X_2} = H_{U, C_U},
\]

which proves the claim of the proposition.

\[\square\]

**Proposition 6.** For any decision set \( U \in \mathcal{C} \) such that \( U \neq U^* \), and any arm \( i \in (U \oplus U^*) \), we have \( \mathcal{H}_i^1 \geq H_{U, C_U} \).

**Proof.** Let us construct a sequence of decision sets \( \{X_1, \ldots, X_p\} \) such that \( X_1 = U \), for all \( j \in \{2, \ldots, p-1\}, X_{j+1} = C_{X_j} \), and \( X_p = U^* \). This sequence is well-defined and has at least two elements, since \( U \neq U^* \) and \( U^* \) is unique. If we prove that for all \( j \in \{2, \ldots, p\} \), we have that for all \( i \in \{X_1 \oplus X_j\} \), \( \mathcal{H}_i^1 \geq H_{X_1, X_2} \), then \( j = p \) will give us the proof of the proposition. Now let us prove this statement. The proof is by induction on \( j \).

**Base Step:** \( j = 2 \). In this case, the claim follows directly from Proposition 5.

**Inductive Step:** Here we assume that for \( j = j' \), we have that \( \mathcal{H}_i^1 \geq H_{X_1, X_2} \), \( \forall i \in (X_1 \oplus X_{j'}) \), and we want to show that \( \mathcal{H}_i^1 \geq H_{X_1, X_2}, \forall i \in (X_1 \oplus X_{j'+1}) \). From Proposition 5 and the construction of the sequence, we have \( \mathcal{H}_i^1 \geq H_{X_{j'}, X_{j'+1}}, \forall i \in (X_{j'} \oplus X_{j'+1}) \). By repeated application of Proposition 4, we can show that \( \forall i \in (X_1 \oplus X_{j'}) \cup (X_{j'} \oplus X_{j'+1}) \), we have \( \mathcal{H}_i^1 \geq \min(H_{X_1, X_{j'}}, H_{X_{j'}, X_{j'+1}}) \geq H_{X_1, X_2} \). Moreover, from Proposition 4, we know that \( X_1 \oplus X_{j'+1} \subseteq (X_1 \oplus X_{j'}) \cup (X_{j'} \oplus X_{j'+1}) \), and thus, we obtain \( \forall i \in (X_1 \oplus X_{j'+1}) \) that \( \mathcal{H}_i^1 \geq H_{X_1, X_2} \), which proves the inductive step.

\[\square\]

We are now ready to prove the main result of this section, the equivalence of the different notions of arm complexity.

**Lemma 3.** For any arm \( i \in \mathcal{K} \), we have \( H_i = \mathcal{H}_i^1 = \mathcal{H}_i^2 \).

\[\text{Note that such a sequence is finite, because by the definition of complement of a decision set, we have } \mu_{X_{j+1}} > \mu_{X_j}, \text{ the number of decision sets is finite, and } i \in U^*.\]
Proof. **Step 1:** We first prove that \( H_i = H_i^1, \forall i \in \mathcal{K}. \)

From the definition of \( H_i^1 \), it is immediate to see that \( H_i^1 \leq \max_{U \in \mathcal{C} : i \in U} H_{U,C_U} = H_i \), and from Proposition 5 we may write \( H_i = \max_{U \in \mathcal{C} : i \in U} H_{U,C_U} \leq H_i^1 \). These together prove Step 1.

**Step 2:** We now want to prove \( H_i^1 = H_i^2, \forall i \in \mathcal{K}. \)

From the definitions of \( H_i^1 \) and \( H_i^2 \), it is immediate to write \( H_i^1 \leq H_i^2 \). To prove the reverse, we consider the following two cases:

**Case 1)** \( i \notin U^* \)

In this case, we may write

\[
H_i^2 = \max_{U \in \mathcal{C} : i \notin U} H_{U,C_U} = \max_{U \in \mathcal{C} : i \notin (U \cup U^*)} H_{U,C_U} \overset{(a)}{=} H_i^1,
\]

where (a) is from Proposition 6.

**Case 2)** \( i \in U^* \)

In this case, we may write

\[
H_i^2 = \max_{U \in \mathcal{C} : i \in U} H_{U,C_U} = \max_{U \in \mathcal{C} : i \in (U \cup U^*)} H_{U,C_U} \overset{(a)}{=} H_i^1,
\]

where (a) is from Proposition 6.

The two cases together prove Step 2.

\[\square\]

**E Proof of Lemma 2**

Let \( U \in \mathcal{C} \) be a decision set with complement \( C_U \). Let \( b \) be an exchange set that satisfies constraints (b)–(e) of Definition 2 for the decision set pair \((U, C_U)\). Let \( V = U \pm b \) be the decision set resulted from applying the transformation \( b \) to \( U \). We now define the exchange set \( d = (C_U \setminus V, V \setminus C_U) \) as the exchange set that completes the transformation of \( U \) to \( C_U \) after applying \( b \) to \( U \). It is easy to show that \( d = (\{C_U \setminus U\} \setminus b_+, \{U \setminus C_U\} \setminus b_-) \). We now prove the following two propositions that are used in the proof of Lemma 2.

**Proposition 7.** For any decision set \( U \in \mathcal{C} \), any exchange set \( b \) that satisfies constraints (b)–(e) of Definition 2 for the decision set pair \((U, C_U)\), and any exchange set \( d \) that completes the transformation of \( U \) to \( C_U \) after applying \( b \) to \( U \), i.e., \( d = (\{C_U \setminus U\} \setminus b_+, \{U \setminus C_U\} \setminus b_-) \), we have

\[
\Delta_{C_U,U} = \Delta_{b_+,b_-} + \Delta_{d_+,d_-} > 0, \tag{24}
\]

\[
\overline{d}_{U,C_U} = \overline{d}_{b_+,b_-} + \overline{d}_{d_+,d_-}. \tag{25}
\]

**Proof.** We begin with the proof of (24). By definition of \( C_U \), \( \mu_{C_U} > \mu_U \), so that \( \Delta_{b_+,b_-} \) and \( \Delta_{d_+,d_-} \) cannot be both negative. Now to prove the equality, first note that \( \mu_{d_+} = \mu_{C_U \setminus U} - \mu_{b_+} \) and \( \mu_{d_-} = \mu_{U \setminus C_U} - \mu_{b_-} \) from the definition of \( d \) and the fact that \( b_+ \subseteq C_U \setminus U \). Further we have \( b_- \subseteq U \subseteq C_U \) from constraints (b) and (c) of Definition 2. Therefore,

\[
\Delta_{C_U,U} = \mu_{C_U} - \mu_U = \mu_{C_U \setminus U} - \mu_{U \setminus C_U} = \left(\mu_{C_U \setminus U} - \mu_{b_+}\right) + \mu_{b_+} - \left(\mu_{U \setminus C_U} - \mu_{b_-}\right) - \mu_{b_-} = \Delta_{b_+,b_-} + \Delta_{d_+,d_-},
\]

which proves (24).

Now let us turn to showing (25):

\[
\overline{d}_{b_+,b_-} + \overline{d}_{d_+,d_-} = |b_+ \oplus b_-| + |d_+ \oplus d_-| \overset{(a)}{=} |b_+| + |b_-| + |d_+| + |d_-| \\
\overset{(b)}{=} |b_+| + |b_-| + |C_U \setminus b_+| + |U \setminus C_U \setminus b_-| \\
\overset{(c)}{=} |b_+| + |b_-| + |C_U \setminus U| - |b_+| + |U \setminus C_U| - |b_-| = |U \oplus C_U| = \overline{d}_{U,C_U},
\]
where (a) comes from the fact that \( b_+ \cap b_- = d_+ \cap d_- = \emptyset \), (b) is from the definition of \( d \), and (e) follows from constraints (b) and (c) of Definition 2.

We are now ready to prove Lemma 2.

**Proof of Lemma 2.** The proof is by contradiction. Suppose \( U \not\perp C_U \). Since independence is symmetric, we also have \( C_U \not\perp U \). This means that there exists a non-empty exchange set \( b = (b_+, b_-) \), different than the independent exchange set \( (C_U \setminus U, U \setminus C_U) \) of \( (U, C_U) \), that satisfies constraints (b)–(e) of Definition 2. From the exchange set \( b \), we define the exchange set \( d \) that completes the transformation of \( U \) to \( C_U \) after applying \( b \) to \( U \) as \( d = ((C_U \setminus U) \setminus b_+, (U \setminus C_U) \setminus b_-) \).

Since \( b \) satisfies constraints (b) and (c), we may write

\[
\mu_{C_U \setminus b} = \mu_{C_U} - \mu_{b_+} + \mu_{b_-} = \mu_{C_U} - \Delta_{b_+, b_-},
\]

which gives

\[
\Delta_{C_U \setminus b, U} = \mu_{C_U \setminus b} - \mu_U = \Delta_{C_U, U} - \Delta_{b_+, b_-}.
\]

(26)

Since \( b \) is not empty, \( C_U \not\perp b \) is closer to \( U \) than \( C_U \), and hence, \( \overline{d}_{U, C_U \setminus b} < \overline{d}_{U, C_U} \). Now consider the following three cases (note that as shown in Proposition 7, \( \Delta_{b_+, b_-} \) and \( \Delta_{d_+, d_-} \) cannot be both negative):

**Case 1** \( \Delta_{b_+, b_-} \leq 0 \)

In this case, by (26) we may write

\[
H_{U, C_U \setminus b} = \frac{\overline{d}_{U, C_U \setminus b}^2}{\Delta_{U, C_U \setminus b}^2} = \frac{\overline{d}_{U, C_U \setminus b}^2}{(\Delta_{U, C_U} - \Delta_{b_+, b_-})^2} \leq \frac{\overline{d}_{U, C_U}^2}{\Delta_{U, C_U}^2} < \frac{\overline{d}_{U, C_U}^2}{\Delta_{U, C_U}^2} \leq \min_{V \in \mathcal{C}_U: \mu_U > \mu_V} H_{U, V},
\]

(27)

where (a) comes from the fact that \( \overline{d}_{U, C_U \setminus b} < \overline{d}_{U, C_U} \) and (b) is from the definition of the complement \( C_U \). Moreover, in this case, from (26), we have \( \Delta_{C_U, U} \leq \Delta_{C_U \setminus b, U} \), which gives us \( \mu_{C_U} \leq \mu_{C_U \setminus b} \). Since \( \mu_U < \mu_{C_U} \) by definition, we have that \( (C_U \setminus b) \in \{ V \in \mathcal{C} : \mu_V > \mu_U \} \) and hence \( H_{U, C_U \setminus b} \geq H_{U, C_U} \) by definition of \( C_U \), which contradicts equation (27).

**Case 2** \( \Delta_{b_+, b_-} > 0 \) and \( \Delta_{d_+, d_-} \leq 0 \)

Here we first show that

\[
\mu_{U \pm b} = \mu_{U \setminus b_+ \cup b_+} = \mu_U - \mu_{b_-} + \mu_{b_+} = \mu_U + \Delta_{b_+, b_-},
\]

where (a) comes from constraints (b) and (c) of Definition 2 which gives us

\[
\Delta_{U \pm b, U} = \mu_{U \pm b} - \mu_U = \Delta_{b_+, b_-}.
\]

(28)

It is also straightforward to see that

\[
\overline{d}_{U, U \pm b} = |U \pm b| = \overline{d}_{b_+, b_-}.
\]

(29)

Now similar to (27), we may write

\[
H_{U, U \pm b} = \frac{\overline{d}_{U, U \pm b}^2}{\Delta_{U, U \pm b}^2} = \frac{\overline{d}_{b_+, b_-}^2}{(\Delta_{b_+, b_-} + \Delta_{d_+, d_-})^2} \leq \frac{\overline{d}_{U, C_U}^2}{\Delta_{U, C_U}^2} \leq \min_{V \in \mathcal{C}_U: \mu_U > \mu_V} H_{U, V},
\]

(30)

where (a) comes from (28) and (29), (b) is from the fact that \( \overline{d}_{d_+, d_-} > 0 \) and \( \Delta_{d_+, d_-} \leq 0 \), and finally (c) is from Proposition 7. Moreover, since \( \Delta_{b_+, b_-} > 0 \), from (28) we have \( \mu_U < \mu_{U \pm b} \), which means that \( (U \pm b) \in \{ V \in \mathcal{C} : \mu_V > \mu_U \} \), and thus, \( H_{U, U \pm b} \) should be bigger than or equal to \( H_{U, C_U} \), which contradicts equation (30).

**Case 3** \( \Delta_{b_+, b_-} > 0 \) and \( \Delta_{d_+, d_-} > 0 \)

From Proposition 7 we have

\[
H_{U, C_U} = \frac{(\overline{d}_{b_+, b_-} + \overline{d}_{d_+, d_-})^2}{(\Delta_{b_+, b_-} + \Delta_{d_+, d_-})^2} \geq \min \left( \frac{\overline{d}_{b_+, b_-}^2}{\Delta_{b_+, b_-}^2}, \frac{\overline{d}_{d_+, d_-}^2}{\Delta_{d_+, d_-}^2} \right) = \min(H_{b_+, b_-}, H_{d_+, d_-}),
\]

where (a) comes from footnote 10, Appendix C. The inequality in (31) is strict whenever \( H_{b_+, b_-} \neq H_{d_+, d_-} \). We now consider the following three cases that all end up contradicting that \( C_U = \arg \min_{V \in \mathcal{C}_U: \mu_U > \mu_V} H_{U, V} \).
Case 3.1) \( H_{b_+,b_-} < H_{d_+,d_-} \)

From equation 31, we have \( H_{U,C_U} > H_{b_+,b_-} \) \( \equiv \) \( H_{U,U} \), where (a) is from 28 and 29. At the same time we have \( H_{U,C_U} = \arg\min_{V:|V|>\mu_U} H_{U,V} \) \( \equiv \) \( H_{U,U} \), which leads to a contradiction. Note that (b) holds because \( \Delta_{b_+,b_-} > 0 \), and thus, \( \mu_U < \mu_{U,U} \) from 28.

Case 3.2) \( H_{b_+,b_-} > H_{d_+,d_-} \)

From equation 31, we have \( H_{U,C_U} > H_{d_+,d_-} \). Since \( d_- \subseteq U \) and \( d_+ \cap U = \emptyset \) from the definition of \( d \), we may write

\[
\Delta_{U,d,U} = \mu_{U,d} - \mu_U = \mu_{U} - \mu_{d_-} + \mu_{d_+} - \mu_{d_-} = \Delta_{d_+,d_-},
\]

and

\[
\Delta_{U,d,U} = \Delta_{d_+,d_-},
\]

which gives us \( H_{U,C_U} > H_{d_+,d_-} = H_{U,d,U} \). At the same time \( H_{U,C_U} = \arg\min_{V:|V|>\mu_U} H_{U,V} \leq H_{U,d,U} \), which leads to a contradiction.

Case 3.3) \( H_{b_+,b_-} = H_{d_+,d_-} \)

From equation 31, we have \( H_{U,C_U} \geq H_{b_+,b_-} \). If the inequality is strict, then we obtain the contradiction as in Case 3.1. Thus let us assume that \( H_{U,C_U} = H_{b_+,b_-} \). From 28 and 29, we have \( H_{U,C_U} = H_{b_+,b_-} = H_{U,U} \), and from 28 and the fact that \( \Delta_{b_+,b_-} > 0 \), we have \( \mu_{U,U} > \mu_U \), and from 25 and 29, we have \( \Delta_{U,U} < \Delta_{U,C_U} \). This creates a contradiction because in case \( H_{U,C_U} = H_{U,U \pm b} \), according to Definition 4, the tie should be broken in favor of the set with the smaller symmetric distance, and thus, \( C_U \) should be \( U \pm b \).

\[ \Box \]

F Proof of Theorem 3

We begin this section with the definition of the \( \ast \)-complement of a decision set. For this, let \( Q(U) \) be the set of decision sets \( V \) such that \( U \perp V \) and the exchange set \( b = (V \setminus U, U \setminus V) \) satisfies constraints (b)-(e) of Definition 2 for the pair of decision sets \( (U, U^*) \).

Definition 8. The \( \ast \)-complement of a decision set \( U \in C \) with \( U \neq U^* \), denoted by \( C_U^\ast \), is defined as

\[
C_U^\ast = \arg\min_{V:Q(U)} H_{U,V}.
\]

We have to show that the argument of the \( \arg\min \) in Definition 8 is not empty, i.e., \( Q(U) \neq \emptyset \). For this purpose, we build a sequence of decision sets \( \{V_1, \ldots, V_p\} \) such that \( V_1, \ldots, V_{p-1} \) are all not independent of \( U \) and \( U \perp V_p \), that is, we stop the sequence as soon as we reach a decision set \( V_p \) independent from \( U \). To construct such a sequence, we start with \( V_1 = U^\ast \) and for \( k \in \{1, \ldots, p-1\} \), we generate \( V_{k+1} = U \pm b_{k+1} \), where \( b_1 = (b_{1,+}, b_{1,-}) = (U^\ast \setminus U, U^\ast \setminus U) \) and \( b_{k+1} = (b_{k+1,+}, b_{k+1,-}) \subseteq b_k = (b_k+, b_k\_\_) \) is an exchange set that satisfies constraints (b)-(e) of Definition 2 for the pair of decision sets \( (U, V_k) \). Note that \( b_{k+1} \) exists by definition as \( V_k \) is not independent of \( U \) and this is why we can build iteratively the sequence \( \{V_1, \ldots, V_p\} \) until we find \( V_p \) with \( U \perp V_p \). Since \( V_{k+1} = U \pm b_{k+1} \), we have \( |V_{k+1} \setminus U| = |(b_{k+1,+} \pm b_{k+1,-})| < |V_k \setminus U| \), which means that the size of the exchange sets \( b_k \) is decreasing, and thus, the sequence eventually has to end. From the construction of the \( b_k \)’s, it is clear that they are all subsets of \( b_1 = (U^\ast \setminus U, U^\ast \setminus U) \), and thus, \( (V_p \setminus U, U \setminus V_p) \) satisfies constraints (b)-(e) of Definition 2 for the pair of decision sets \( (U, U^\ast) \). This proves that \( Q \neq \emptyset \) and the argument of the \( \arg\min \) in Definition 8 is not empty. Also, note that \( \mu_{C_U^\ast} > \mu_U \) as intuitively \( C_U^\ast \) is a decision set made by replacing parts of \( U \) by parts of \( U^\ast \).

We are now ready to give the proof of Theorem 3.

\[ \text{Proof of Theorem 3} \]

We only consider the case where \( i \not\in U^\ast \) in detail, the case \( i \in U^\ast \) is symmetric. Let \( H_{i,U}^\ast 

1^2\text{Note that since } U \perp V, \text{ the exchange set } b = (V \setminus U, U \setminus V) \text{ is the only non-empty exchange set that satisfies constraints (b)-(e) of Definition 2 for the pair of decision sets } (U, C_U).
Therefore, we have the following series of inequalities

$$ H_i = (a) = \mathcal{H}^2_i = (b) \max_{U,C_U} H_{U,C_U} \leq (c) \max_{U,C_U} H_{U,C_U} = (d) \max_{U,C_U \in U} H_{U,C_U} = (e) \max_{U,V} H_{U,V}, $$

where (a) holds by Lemma 3 (b) uses the definition of \( \mathcal{H}^2_i \), (c) uses \( H_{U,C_U} = \min_{\mathcal{V}} H_{U,V} \leq H_{U,C_U} \) as \( \mu_{C_U} > \mu_U \), (d) uses the equivalence of complexity based on the *complement, (e) introduces \( U_i \) to denote the decision set attaining the maximum in the above equation and \( \mathcal{V}_i = \mathcal{C}_U_i \). By the definition of the *complement, \( \mathcal{V}' = (\mathcal{V}_i \setminus \mathcal{U}_i \setminus \mathcal{V}_i) \) satisfies constraints (b)-(e) of Definition 2 for the pair of decision sets \((U, \mathcal{U}^*) \). As a result, \( \mathcal{U}^* \cap \mathcal{V}' \in \mathcal{C} \) and \( i \in \mathcal{U}_i \cap \mathcal{V}' \) (see constraint (e) in Definition 2 and \( \bar{V}_i \)). By the definition of \( \mathcal{V}_i \), we have \( \mu_{U_i} = \mu_{V_i} + \mu_{V_i} - \mu_{V_i} \), and thus, we may write

$$ \Delta_{\mathcal{V}_i, \mathcal{U}_i} = \mu_{V_i} - \mu_{V_i} = \mu^* - (\mu^* - \mu_{V_i} + \mu_{V_i}) = \Delta_{\mathcal{U}_i, \mathcal{V}_i} \geq \min_{U_i \in \mathcal{U}} \Delta_{\mathcal{U}_i, \mathcal{V}_i}, $$

where the last inequality follows from the fact that \( i \in \mathcal{U}_i \). We note that for any independent pair of sets such as \( \mathcal{V}_i, \mathcal{U}_i \), any well defined exchange class \( \mathcal{B} \) should include the (unique) exchange set \( \mathcal{V}' = (\mathcal{V}_i \setminus \mathcal{U}_i \setminus \mathcal{V}_i) \) that allows to move from one set to another. As a result for any exchange class \( \mathcal{B} \), width(\( \mathcal{B} \)) = \( \max_{(b_+, b_-) \in \mathcal{B}} |b_+| + |b_-| = |b_+| + |b_-| = |U_i \cap \mathcal{V}_i| = \Delta_{\mathcal{U}_i, \mathcal{V}_i} \). Therefore, width(\( \mathcal{C} \)) = \( \min_{\mathcal{B} \in \text{Exchange}(\mathcal{C})} \) width(\( \mathcal{B} \)) \( \geq \Delta_{\mathcal{U}_i, \mathcal{V}_i} \), which together with \( \Delta_{\mathcal{V}_i, \mathcal{U}_i} \geq \min_{U_i \in \mathcal{U}} \Delta_{\mathcal{U}_i, \mathcal{V}_i} \) leads to the desired outcome

$$ H_i \leq \frac{\Delta_{\mathcal{V}_i, \mathcal{U}_i}}{\Delta_{\mathcal{V}_i, \mathcal{U}_i}} \leq \frac{\text{width}(\mathcal{C})}{\min_{U_i \in \mathcal{U}} \Delta_{\mathcal{U}_i, \mathcal{V}_i}} \leq H_i. $$

\( \square \)

### G Fixed Budget Results: Proof of Theorem 1

In this section, we provide a proof of Theorem 1. In the following, we will mainly work with the complexity \( \mathcal{H}^2_i \) (and the corresponding simplicity \( G \)) as defined in equation (7). Recall that this formulation is equivalent to \( H_i \). In the following, we use \( [N] \) to denote the set \( \{1, 2, \ldots, N\} \). We also introduce two numerical constants \( 0 < c_1 < 1 \) and \( 0 < c_2 < 1/2 \) such that \( c_2 \geq \frac{c_1}{1 - c_1} \geq c_2 \), whose exact values will be chosen later. Finally, we consider a permutation \( \pi \) of the arms that orders the arms with respect to the values \( G_i \), that is, \( G_{\pi(1)} \geq G_{\pi(2)} \geq \ldots \geq G_{\pi(K)} \). To simplify notation, in the following, we will simply write \( G_{\pi(i)} \) instead of \( G_{\pi(i)} \).

We now introduce a high-probability event which serves as a basis for the proof of the correctness of the algorithm. This event states that at the end of each phase \( k \) the estimated values of the arms will differ from their real values by at most \( G(k) \).

**Lemma 4.** Let \( G_{\pi(1)} \geq G_{\pi(2)} \geq \ldots \geq G_{\pi(K)} \) be an ordering of arms by decreasing complexity.\[13\] The event \( \xi \) defined as

$$ \xi = \{ \forall i \in K, k \in [K], |\hat{\mu}_i(k) - \mu_i| \leq c_1 G(k) \} \tag{32} $$

holds with probability

$$ P(\xi) \geq 1 - 2K^2 \exp \left( - \frac{2c_1^2(n - K)}{\log(K)H} \right). $$

**Proof.** By Hoeffding’s inequality and a union bound, the probability of the complementary event \( \bar{\xi} \) of \( \xi \) can be bounded as

\[13\]Notice that the \( i \)-th simplest arm is the \((K + 1 - i)\)-th most complex arm.
Lemma 4. We start with concentration inequalities on event \( \xi \).

We continue with a few properties implied by the induction hypothesis together with the high-probability event \( \text{arm} \).

Definition 9. The induction hypothesis is defined by the two following properties. At the beginning of phase \( k \) we have:

(i) All accepted arms belong to the optimal set, i.e., \( J_n(k - 1) \subseteq U^* \), and all rejected arms (i.e., arms which have been deactivated but never accepted) do not belong to the optimal set, i.e., \( (K_k \setminus J_n(k - 1)) \cap U^* = \emptyset \).

(ii) If arm \( i \notin K_k \) and it has been deactivated during phase \( l \in [k - 1] \), then \( G_i \geq (1 - 2c_2)G(l) \).

Statement (i) is the classical desired property, while statement (ii) is specific to our approach and implies that by having been pulled \( n_i \) times the arm \( i \) has been sampled sufficiently often w.r.t. its complexity. Indeed, recall that a set is not necessarily compared to the optimal set \( U^* \) whose arms most probably belongs to \( K_k \). Therefore we need to show that an arm \( i \) contained in a set \( V \) that is likely to be used as a complement set by some “active” set \( U \) has been sampled often enough (i.e., proportionally to its complexity \( H_i \)), especially if it has been removed in a previous phase \( l < k \).

We will now prove Theorem 1 by showing that on event \( \xi \) the set returned by the algorithm at the end. On the event \( \xi \) deduced from statement (ii) of the induction hypothesis in Definition 9 below.

For the proof of Theorem 1, we analyze a slightly modified algorithm described in Figure 5, where for each arm that is deactivated but never accepted do not belong to the optimal set, i.e., \( i \in J_n(k - 1) \cap U^* \).

Figure 5: The modified fixed budget algorithm.

follows, provided we use the proposed pulls scheme \( n_k = \left\lceil \frac{n - K}{\log(K)(K + 1 - k)} \right\rceil \), \( k \in K \):

\[
P(\xi) = \sum_{i=1}^{K} \sum_{k=1}^{K} P\left( |\mu_i(k) - \mu_i| > c_1G_i(k) \right)
\leq \sum_{i=1}^{K} \sum_{k=1}^{K} 2 \exp\left( -2n_kc_1^2G_i^2(k) \right)
\leq \sum_{i=1}^{K} \sum_{k=1}^{K} 2 \exp\left( -\frac{2c_1^2(n - K)}{\log(K)(K + 1 - k)H_i(K + 1 - k)} \right)
\leq 2K^2 \exp\left( -\frac{2c_1^2(n - K)}{\log(K)H} \right).
\]

For the proof of Theorem 1 we analyze a slightly modified algorithm described in Figure 5, where for each arm that is deactivated it is immediately (and not only after all arms have been deactivated) decided, whether it shall be contained in the set returned by the algorithm at the end. On the event \( \xi \), the correctness of both algorithms is the same, which can be deduced from statement (ii) of the induction hypothesis in Definition 9 below.

We will now prove Theorem 1 by showing that on event \( \xi \), the optimal set \( U^* \) is identified at the end of the phases. That is, the algorithm neither accepts an arm not in \( U^* \), nor is any arm in \( U^* \) rejected.

G.1 The Induction Hypothesis

The proof proceeds by induction over the phases of the algorithm. We first introduce the induction hypothesis.

Definition 9. The induction hypothesis is defined by the two following properties. At the beginning of phase \( k \) we have:

(i) All accepted arms belong to the optimal set, i.e., \( J_n(k - 1) \subseteq U^* \), and all rejected arms (i.e., arms which have been deactivated but never accepted) do not belong to the optimal set, i.e., \( (K_k \setminus J_n(k - 1)) \cap U^* = \emptyset \).

(ii) If arm \( i \notin K_k \) and it has been deactivated during phase \( l \in [k - 1] \), then \( G_i \geq (1 - 2c_2)G(l) \).

We continue with a few properties implied by the induction hypothesis together with the high-probability event \( \xi \) of Lemma 4. We start with concentration inequalities on event \( \xi \) for \( \hat{\mu}, \Delta, \) and \( \hat{G} \).
Proposition 8. Assume that the induction hypothesis (Definition 9) at the beginning of phase $k$ as well as event $\xi$ hold. Then for any arm $i \in \mathcal{K}$,

$$|\hat{\mu}_i(k) - \mu_i| \leq c_1 \max \left\{ \frac{G_{i}}{1 - 2c_2}, G_{(k)} \right\},$$

(33)

Furthermore for any pair $(U, V) \in \mathcal{C}^2$ such that $V = \mathcal{C}_U$ we have

$$|\hat{\Delta}_{V,U}(k) - \Delta_{V,U}| \leq c_2 \tilde{d}_{U,V} \max\{G_{V,U}, G_{(k)}\}$$

and

$$|\hat{G}_{V,U}(k) - G_{V,U}| \leq c_2 \max\{G_{V,U}, G_{(k)}\}.$$

where $\hat{\Delta}_{V,U}(k)$ and $\hat{G}_{V,U}(k)$ are the gaps and the simplicity computed at the end of the phase $k$. Finally, for the special case of pairs $(U^*, U)$,

$$|\hat{\Delta}_{U^*,U}(k) - \Delta_{U^*,U}| \leq c_2 \tilde{d}_{U^*,U^*} \max\{G_{U^*,U}, G_{(k)}\}$$

and

$$|\hat{G}_{U^*,U}(k) - G_{U^*,U}| \leq c_2 \max\{G_{U^*,U}, G_{(k)}\},$$

with $V = \mathcal{C}_U$.

Proof. First note that if $i \in \mathcal{K}_k$, then on event $\xi$ we have $|\hat{\mu}_i(k) - \mu_i| \leq c_1 G_{(k)}$. Thus, let us assume that $i \notin \mathcal{K}_k$. Let $l$ be the phase at which arm $i$ has been deactivated, with $l \in \{1, \ldots, k - 1\}$. We have

$$|\hat{\mu}_i(k) - \mu_i| \leq c_1 G_{(l)} \leq c_1 \frac{1}{1 - 2c_2} G_i,$$

where (a) is implied by the event $\xi$ and the fact that $\hat{\mu}_i(k) = \hat{\mu}_i(l)$, (b) uses property (ii) of the induction hypothesis. Summarizing, independent of whether $i \in \mathcal{K}_k$ or not, we have for any $i$

$$|\hat{\mu}_i(k) - \mu_i| \leq c_1 \max \left\{ \frac{G_{i}}{1 - 2c_2}, G_{(k)} \right\},$$

which shows the first claim. Let us now focus on a pair of sets $U, V$ such that $i \in U \oplus V$ and $V = \mathcal{C}_U$ or $V = U^*$. Then by the previous inequality,

$$|\hat{\mu}_i(k) - \mu_i| \leq c_1 \max \left\{ \frac{G_{i}}{1 - 2c_2}, G_{(k)} \right\} \leq \max \{ c_2 G_i, c_1 G_{(k)} \} \leq c_2 \max\{G_{V,U}, G_{(k)}\},$$

where (a) follows from the choice of the constants such that $c_2 \geq \frac{c_1}{1 - 2c_2}$. For (b) we use Proposition 5 for $V = \mathcal{C}_U$, the definition of $G_{V,U}$, the fact that $\Delta_{V,U} > 0$ as well as $c_1 \leq c_2$. As a result we obtain

$$|\hat{\Delta}_{V,U}(k) - \Delta_{V,U}| \leq \sum_{i \in U \oplus V} |\hat{\mu}_i(k) - \mu_i| \leq c_2 \tilde{d}_{V,U} \max\{G_{V,U}, G_{(k)}\},$$

which proves the first part of the second statement. The second part then simply follows from

$$\hat{G}_{V,U}(k) = \frac{\hat{\Delta}_{V,U}(k)}{\tilde{d}_{V,U}} \geq \frac{\Delta_{V,U} - c_2 \tilde{d}_{V,U} \max\{G_{V,U}, G_{(k)}\}}{\tilde{d}_{V,U}} = G_{V,U} - c_2 \max\{G_{V,U}, G_{(k)}\},$$

where (c) follows from the first statement. The missing inequality to conclude the second part of the second statement can be obtained analogously. Finally, the last statement follows along the same lines, only replacing Proposition 5 in step (b) above by Proposition 9. \qed
The following Proposition shows that at the beginning of each phase $k$ there is an arm $a_k$ which has a larger simplicity than the $k$-th largest simplicity. In the remaining proof this arm will serve as a reference arm, as this is the arm that should be deactivated at the end of phase $k$.

**Proposition 9.** Let

$$a_k = \arg \min_{i \in K_k} H_i = \arg \max_{i \in K_k} G_i$$

be the simplest arm among those left at the beginning of phase $k$. Then $G_{a_k} \geq G_{(k)}$.

**Proof.** At the beginning of phase $k$, only $K - |K_k| = k - 1$ arms have been deactivated, i.e., $|K_k| = K + 1 - k$. Hence the simplest arm left in $K_k$ (i.e., $a_k$) cannot be more difficult than the arm that would be left if all the $k - 1$ simpler arms were deactivated (i.e., $G_{(k)}$), which gives the claimed $G_{a_k} \leq G_{(k)}$.

The following Proposition shows that at the end of each phase $k$, the reference arm $a_k$ belongs to $\hat{U}^*$ if and only if it actually belongs to $U^*$. This allows us to show that the simplicity of $a_k$ can be well estimated at the end of phase $k$.

**Proposition 10.** Assume that the induction hypothesis (Definition 9) at the beginning of phase $k$ as well as event $\xi$ hold. Then $a_k \in U^*$ if and only if $a_k \in \hat{U}^*(k)$, where $\hat{U}^*(k)$ is the estimated optimal set at the end of phase $k$.

**Proof.** We prove in detail that $a_k \not\in U^*$ implies $a_k \not\in \hat{U}^*(k)$. The reverse can be shown along a similar line of arguments. The proof is by contradiction. Thus, let us assume that $a_k \not\in U^*$ and $a_k \in \hat{U}^*(k)$. Note that this implies that $\hat{U}^*(k) \neq U^*$. Let $W = C_{\hat{U}^*(k)}$ be the complement of the estimated optimal set (note that $W$ exists, since $\hat{U}^*(k)$ is not optimal). We have

$$\Delta_{W,\hat{U}^*(k)}^{(a)} \geq \Delta_{W,\hat{U}^*(k)} - c_2 \bar{d}_{W,\hat{U}^*(k)} \max \left\{ G_{W,\hat{U}^*(k)}, G_{(k)} \right\}$$

$$= \bar{d}_{W,\hat{U}^*(k)} \left( G_{W,\hat{U}^*(k)} - c_2 \max \left\{ G_{W,\hat{U}^*(k)}, G_{(k)} \right\} \right),$$

where (a) uses Proposition 8. We consider two cases.

**Case 1** $G_{W,\hat{U}^*(k)} \geq G_{(k)}$

In this case,

$$\Delta_{W,\hat{U}^*(k)} \geq \bar{d}_{W,\hat{U}^*(k)} \left( G_{W,\hat{U}^*(k)} - c_2 G_{W,\hat{U}^*(k)} \right)$$

$$= \bar{d}_{W,\hat{U}^*(k)} G_{W,\hat{U}^*(k)} (1 - c_2) > 0,$$

where the last inequality follows from the fact that $0 < c_2 < 1$ and $G_{W,\hat{U}^*(k)} > 0$ by definition of $W$. It follows that $\hat{\mu}_{\hat{U}^*(k)}(k) < \hat{\mu}_W(k)$, which contradicts that $\hat{U}^*(k)$ is the empirical best set.

**Case 2** $G_{W,\hat{U}^*(k)} < G_{(k)}$

We write

$$\Delta_{W,\hat{U}^*(k)} \geq \bar{d}_{W,\hat{U}^*(k)} \left( G_{W,\hat{U}^*(k)} - c_2 G_{(k)} \right)$$

$$\geq \bar{d}_{W,\hat{U}^*(k)} \left( a_k - c_2 G_{(k)} \right)$$

$$\geq \bar{d}_{W,\hat{U}^*(k)} G_{(k)} (1 - c_2) > 0,$$

where (b) holds since $a_k \in \hat{U}^*(k)$, so that $G_{a_k} = \min_{U \in K_k} \max_{V \in \mu_U > \mu_V} G_{V,\hat{U}^*(k)} \leq \max_{V \in \mu_U > \mu_V} G_{V,\hat{U}^*(k)} = G_{W,\hat{U}^*(k)}$. Concerning (c), this holds by Proposition 8 as $G_{a_k} \geq G_{(k)}$. Similar as before we obtain the contradiction $\hat{\mu}_{\hat{U}^*(k)}(k) < \hat{\mu}_W(k)$. \qed

The following Proposition gives a lower bound on the estimated simplicity of the reference arm $a_k$ at the end of phase $k$ depending on $G(k)$. This will be used later to show that the algorithm does not remove other arms than $a_k$ in each phase $k$. 

---

**Improved Learning Complexity in Combinatorial Pure Exploration Bandits**

---
Proposition 11. Assume that the induction hypothesis (Definition 9) at the beginning of phase $k$ as well as event $\xi$ hold. Then $\hat{G}_{\alpha_k}(k) \geq (1 - c_2)G(k)$.

Proof. We give a detailed proof for the case where $a_k \notin \hat{U}^*(k)$. The other case follows from symmetric arguments. Let $U_k$ be a set that defines the estimated simplicity of $a_k$, that is

$$U_k \in \arg \min_{U:a_k \in U} \hat{G}_{\mathcal{C}(U),U_k}(k),$$

and let $W_k = C_{U_k}$. Note that $W_k$ is well-defined because $U_k \neq U^*$: Indeed, from Proposition 10 since $a_k \notin \hat{U}^*(k)$, also $a_k \notin U^*$, so that because $a_k \in U_k$, we have $U_k \neq U^*$.

Then we have

$$\hat{G}_{\alpha_k}(k) = \hat{G}_{\mathcal{C}(U),U_k}(k) = \max_{V:\hat{\mu}_V(k) > \hat{\mu}_{U_k}(k)} \hat{G}_{V,U_k}(k) \geq \hat{G}_{W_k,U_k}(k) \geq c_2 \max \{G_{W_k,U_k}, G(k)\},$$

where (a) follows from Proposition 8. We have, as $a_k \notin U^*$, that

$$G_{\alpha_k} = \min_{U:a_k \in U} G_{\mathcal{C}(U),U} \leq G_{W_k,U_k}.$$

Furthermore, from Proposition 9 we have that $G(k) \leq G_{\alpha_k}$ and thus $G(k) \leq G_{W_k,U_k}$. Thus the previous expression simplifies to

$$\hat{G}_{\alpha_k}(k) \geq G_{W_k,U_k} - c_2 G_{W_k,U_k} \geq (1 - c_2)G(k).$$

The following lemma is rather technical. It shows that if the estimated simplicity of a sub-optimal decision $U_k$ is defined with respect to $V_k$, then this estimated simplicity will be larger than the true simplicity of the decision set $V_k$. The proof shows that if the estimated simplicity of $U_k$ were smaller than the true simplicity of $V_k$, then it would surely be also smaller than the estimated simplicity of $V_k$ defined with respect to $W_k$, leading to a contradiction. For notational convenience, in the following we will drop the dependency of the estimated quantities on the phase $k$ (e.g., write $\hat{G}_{\mathcal{V}_k}$ instead of $\hat{G}_{\mathcal{V}_k,U_k}(k)$).

Proposition 12. Assume that the induction hypothesis (Definition 9) at the beginning of phase $k$ as well as event $\xi$ hold. Further assume that $U_k, V_k, W_k \in C$ such that $U_k \neq \hat{U}^*(k)$, $V_k = C_{U_k}(k) \neq U^*$, $W_k = C_{V_k}$, and $G_{W_k,V_k} \geq G(k)$. Then $\hat{G}_{\mathcal{V}_k,U_k}(k) \geq (1 - c_2)G_{W_k,V_k}$.

Proof. We start by showing that $\hat{\mu}_{U_k} < \hat{\mu}_{\mathcal{V}_k} < \hat{\mu}_{W_k}$. First, $\hat{\mu}_{U_k} < \hat{\mu}_{V_k}$ comes from the definition of $V_k$ as the (estimated) complement of $U_k$. Furthermore,

$$\Delta_{W_k,V_k} \geq \Delta_{W_k,V_k} - c_2 d_{W_k,V_k} \max \{G_{W_k,V_k}, G(k)\} \geq \Delta_{W_k,V_k} - c_2 d_{W_k,V_k} G_{W_k,V_k} \geq \Delta_{W_k,V_k} - c_2 \Delta_{W_k,V_k} > 0,$$

where (a) follows from Proposition 8 and the fact that $\Delta_{W_k,V_k} > 0$ (since $W_k$ is the (exact) complement of $V_k$), (b) follows from the assumption that $G_{W_k,V_k} \geq G(k)$, and (c) is obtained from the definition of simplicity $G_{W_k,V_k}$ and the fact that $0 < c_2 < 1$. This completes the proof of the claim that $\hat{\mu}_{U_k} < \hat{\mu}_{V_k} < \hat{\mu}_{W_k}$.
Next, we show that $\hat{G}_{W_k,V_k} \leq \hat{G}_{V_k,U_k}$. First note that by Proposition 8, we obtain from $\hat{\mu}_{U_k} < \hat{\mu}_{V_k} < \hat{\mu}_{W_k}$ that $\hat{G}_{W_k,V_k} \leq \min \left\{ \hat{G}_{W_k,V_k}, \hat{G}_{V_k,U_k} \right\}$, where the inequality is strict whenever $G_{W_k,V_k} \neq \hat{G}_{V_k,U_k}$. Now if we assume that $\hat{G}_{W_k,V_k} > \hat{G}_{V_k,U_k}$, the previous inequality becomes strict as $\hat{G}_{W_k,U_k} > \hat{G}_{V_k,U_k}$. Then we would obtain the contradiction

$$\hat{G}_{V_k,U_k} = \max_{V: \hat{\mu}_V > \hat{\mu}_U} \hat{G}_{V,U} \geq \hat{G}_{W_k,U_k} > \hat{G}_{V_k,U_k},$$

thus implying the claimed $\hat{G}_{W_k,V_k} \leq \hat{G}_{V_k,U_k}$.

We now can conclude with

$$\hat{G}_{V_k,U_k} \geq \hat{G}_{W_k,V_k} \begin{cases} \geq G_{W_k,V_k} - c_2 \max \{G_{W_k,V_k}, G(k)\} \\
\geq G_{W_k,V_k} - c_2 G_{W_k,V_k}, \end{cases}$$

where (a) follows from Proposition 8 and the fact that $\Delta_{W_k,V_k} > 0$ and (b) holds due to the assumption that $G_{W_k,V_k} \geq G(k)$.

\[\Box\]

### G.2 The Induction Step

We now move on to prove the induction step. We do this in two separate lemmas, one for each property in the induction hypothesis.

**Lemma 5.** Assume that the induction hypothesis at the beginning of phase $k$ as well as event $\xi$ hold. Then property (i) of Definition 9 holds at phase $k + 1$ as well.

**Proof.** Property (i) states that no error is made until the beginning of phase $k$. To prove that this is still true at the beginning of phase $k + 1$ we need to prove that during phase $k$ no error is made. An error occurs when either the algorithm deactivates and rejects an arm $j_k \in U^*$, or the algorithm deactivates and accepts an arm $j_k \notin U^*$. We show by contradiction that both cases cannot happen.

We give a detailed proof for the case where $j_k \in U^*$ is rejected. The argument for the second source of error, when $j \notin U^*$ is accepted, is similar.

The strategy of the proof will be to compare the estimated simplicity of the rejected arm to the simplicity of the arm $a_k$, that is, the arm with the highest simplicity at the end of phase $k$, and which should be the targeted arm to be deactivated. Using Proposition 11 we know that the simplicity of $a_k$ is of order of $G(k)$. Therefore it remains to prove that $G_{j_k}$ is smaller than $G(k)$.

As $j_k$ is rejected, $j_k \notin \hat{U}^*(k)$ and hence, $U^* \neq \hat{U}^*$. Furthermore, $a_k \neq j_k$, as otherwise Proposition 10 would imply that $j_k \in \hat{U}^*$, a contradiction to the assumption that arm $j_k$ is rejected.

As $j_k$ has been deactivated during phase $k$, we have $\hat{G}_{j_k} \geq \hat{G}_{a_k}$, since the algorithm deactivates the arm with the largest simplicity, that is, $j_k = \arg \max_{i \in \mathcal{A}_k} \hat{G}_i$. Let $V_k = \hat{C}_U$ be the estimated complement of the optimal set (which exists, as $U^* \neq \hat{U}^*$) and $W_k = \hat{C}_{V_k}$ be the (exact) complement of $V_k$. Then

$$\hat{G}_{j_k} = \min_{U: j \in U} \max_{V: \hat{\mu}_V > \hat{\mu}_U} \hat{G}_{V,U} \begin{cases} \leq \hat{G}_{V_k,U^*} \\
\leq G_{V_k,U^*} + c_2 \max \{G_{W_k,V_k}, G(k)\} \\
\leq c_2 \max \{G_{W_k,V_k}, G(k)\}, \end{cases}$$

where (a) is because $j_k \in U^*$ and $V_k$ is the (estimated) complement of $U^*$, (b) holds by the last statement of Proposition 8 and (c) follows from $\mu_{V_k} < \mu^*$, whence $\Delta_{V_k,U^*} < 0$ and $\hat{G}_{V_k,U^*} < 0$.\footnote{More precisely, we rely on an equivalent version based on estimated values and estimated simplicity.}
We now show by contradiction that $G_{W_k, V_k} \leq G_{(k)}$. Thus, assume that $G_{W_k, V_k} > G_{(k)}$. Then by Proposition 12, $\hat{G}_{V_k, U^*} \geq (1 - c_2)G_{W_k, V_k}$. Together with the previous inequality this gives
\[(1 - c_2)G_{W_k, V_k} \leq \hat{G}_{V_k, U^*} \leq c_2 \max\{G_{W_k, V_k}, G_{(k)}\} \leq c_2G_{W_k, V_k},\]
which is a contradiction, since $c_2 < 1/2$, and we conclude that $G_{W_k, V_k} \leq G_{(k)}$.

Now using inequality (c) from before, we get $\hat{G}_{j_k} \leq c_2G_{(k)}$. Using Proposition 11 for $a_k$ we have that $\hat{G}_{a_k} \geq (1 - c_2)G_{(k)}$. Since $c_2 < 1/2$, it holds that $\hat{G}_{j_k} \leq c_2G_{(k)} < (1 - c_2)G_{(k)} \leq \hat{G}_{a_k}$. As a result $\hat{G}_{j_k} < \hat{G}_{a_k}$, which contradicts the fact that $j_k$ would be the deactivated arm during phase $k$, as by definition of $j_k = \arg\max_{i\in K_k} \hat{G}_i$. Thus we can conclude that the algorithm does not reject any arm from $U^*$.

**Lemma 6.** Assume that the induction hypothesis at the beginning of phase $k$ as well as event $\xi$ hold. Then property (ii) of Definition 5 holds at phase $k + 1$ as well.

**Proof.** Let $j_k$ be the arm which is deactivated at the end of phase $k$, i.e., $j_k = \arg\max_{i\in K_k} \hat{G}_i(k)$. Again, we only consider the case where $j_k \notin U^*$, as the proof for the case $j_k \in U^*$ is symmetrical. We have to show that $j_k$ satisfies $G_{j_k} \geq (1 - 2c_2)G_{(k)}$, which will be done in five steps.

**Step 1.** We first notice that Lemma 5 implies that no error is made during phase $k$, since property (i) still holds at the beginning of phase $k + 1$. As a result, we have that $j_k \in U^*$ if and only if $j_k \in \hat{U}^*$ which means in our current case that $j_k \notin U^*$. Let $U_k$ and $V_k$ be the sets which define the (exact) simplicity of $j_k$, that is,
\[U_k = \arg\min_{U,j_k \in U} G_{C_{U,U}},\]
and $V_k = C_{U_k}$, so that $G_{j_k} = G_{V_k, U_k}$. Further, let $W_k = \hat{C}_{U_k}$, noting that $W_k$ is well defined since $U_k \neq \hat{U}^*$. Indeed, $j_k \notin U^*$ and $j_k \in U_k$, whence $U_k \neq U^*$.

We claim that $G_{W_k, U_k} \leq G_{j_k}$. Indeed, if $\mu_{W_k} \leq \mu_{U_k}$ then we trivially have $G_{W_k, U_k} \leq 0 \leq G_{j_k}$. Furthermore, if $\mu_{W_k} > \mu_{U_k}$, we have by definition of $U_k$ and $V_k$,
\[G_{W_k, U_k} \leq \max_{W:\mu_W > \mu_{U_k}} G_{W, U_k} = G_{V_k, U_k} = G_{j_k},\]
which proves our claim $G_{W_k, U_k} \leq G_{j_k}$.

**Step 2.** Next, we note that
\[\hat{G}_{j_k} = \min_{U, j_k \in U} \hat{G}_{C_{U,U}} \leq \max_{\hat{C}_{U,U} > \mu_{U_k}} \hat{G}_{V_k, U_k} = \hat{G}_{W_k, U_k}.\]

**Step 3.** Here we show that $G_i \leq \max\{G_{j_k}, G_{Z_k, W_k}\}$ for $i \in W_k \oplus U_k$. We distinguish the following cases:

- **Case 1)** \( i \in W_k \setminus U_k \)
  - **Case 1.1)** \( i \in U^* \): In this case \( i \in U_k \oplus U^* \) and thus we can apply Proposition 6 to $U_k$ and $C_{U_k} = V_k$ and obtain $G_i \leq G_{V_k, U_k} = G_{j_k}$.
  - **Case 1.2)** \( i \notin U^* \): Let $Z_k = C_{W_k}$, noting that since $i$ is in $W_k$ but not in $U^*$, we have $W_k \neq U^*$. Then
    \[G_i = \min_{U \in U} G_{C_{U,U}} \leq G_{C_{W_k, W_k}} = G_{Z_k, W_k},\]
    where the first equality follows from the fact that $i \notin U^*$, while the inequality is due to the fact that $i \in W_k$.

- **Case 2)** \( i \in U_k \setminus W_k \)
  - **Case 2.1)** \( i \in U^* \): Let $Z_k = C_{W_k}$, noting that since $i$ is in $U^*$ but not in $W_k$, it holds that $W_k \neq U^*$. Then
    \[G_i = \min_{U \in U} G_{C_{U,U}} \leq G_{C_{W_k, W_k}} = G_{Z_k, W_k},\]
where the first equality follows from the fact that \( i \in U^* \), while the inequality is due to the fact that \( i \notin W_k \).

**Case 2.2** \( i \notin U^* \): In this case we have by definition that
\[
G_i = \min_{U \ni i \in U} G_{C_{U,i}} \leq G_{C_{U,i},U_k} = G_{V_k,U_k} = G_{j_k},
\]
which completes the proof that \( G_i \leq \max\{G_{j_k}, G_{Z_k,W_k}\} \) for \( i \in W_k \oplus U_k \).

**Step 4.** Next, we are going to show that \( \hat{G}_{j_k} \leq G_{j_k} + c_2 \max\{G_{j_k}, \hat{G}_{(k)}\} \), a version of Proposition 8 for arm \( j_k \). We distinguish two cases:

**Case 1** \( W_k = U^* \)

In this case, we have
\[
\hat{G}_{j_k} \leq \hat{G}_{W_k,U_k} \leq \hat{G}_{W_k,U_k} + c_2 \max\{G_{V_k,U_k}, \hat{G}_{(k)}\} \leq G_{j_k} + c_2 \max\{G_{j_k}, \hat{G}_{(k)}\},
\]
where (a) is obtained from equation (34), (b) is a result of Proposition 8 and (c) follows from \( \hat{G}_{W_k,U_k} \leq G_{j_k} \) of Step 1.

**Case 2** \( W_k \neq U^* \)

Let \( Z_k = C_{W_k} \). We prove by contradiction that \( G_{Z_k,W_k} \leq \max\{G_{V_k,U_k}/(1 - 2c_2), \hat{G}_{(k)}\} \). Thus, assume that \( G_{Z_k,W_k} > \max\{G_{V_k,U_k}/(1 - 2c_2), \hat{G}_{(k)}\} \).

Then
\[
\hat{G}_{W_k,U_k} \leq G_{W_k,U_k} + c_1 \frac{1}{d_{U_k \oplus W_k}} \sum_{i \in U_k \oplus W_k} \max\left\{ \frac{G_i}{1 - 2c_2}, \hat{G}_{(k)} \right\}
\]
\[
\leq G_{W_k,U_k} + c_1 \max\left\{ \frac{G_{j_k}}{1 - 2c_2}, \frac{G_{Z_k,W_k}}{1 - 2c_2}, \hat{G}_{(k)} \right\}
\]
\[
\leq G_{V_k,U_k} + c_1 \frac{G_{Z_k,W_k}}{1 - 2c_2}
\]
\[
\leq G_{V_k,U_k} + c_2 G_{Z_k,W_k},
\]
(35)
where (a) is using for all \( i \in U_k \oplus W_k \) the Equation (33) in Proposition 8, (b) follows from Step 3, and (e) is obtained by \( G_{W_k,U_k} \leq G_{j_k} = G_{V_k,U_k} \) (Step 1) and the assumption on \( G_{Z_k,W_k} \), finally (d) is obtained by \( \frac{c_1}{1 - 2c_2} \leq c_2 \). By Proposition 12 we have \( \hat{G}_{W_k,U_k} \geq (1 - c_2)G_{Z_k,W_k} \), which together with (35) gives
\[
(1 - c_2)G_{Z_k,W_k} \leq \hat{G}_{W_k,U_k} \leq G_{V_k,U_k} + c_2 G_{Z_k,W_k} \leq c_2 G_{Z_k,W_k},
\]
which is a contradiction due to \( 0 < c_2 < 1/2 \). This finishes the proof of \( G_{Z_k,W_k} \leq \max\{G_{V_k,U_k}/(1 - 2c_2), \hat{G}_{(k)}\} \).

By (35) and the results of Steps 2 and 1, we finally get
\[
\hat{G}_{j_k} \leq \hat{G}_{W_k,U_k} \leq G_{W_k,U_k} + c_1 \max\left\{ \frac{G_{j_k}}{1 - 2c_2}, \frac{G_{Z_k,W_k}}{1 - 2c_2}, \hat{G}_{(k)} \right\} \leq G_{j_k} + c_2 \max\{G_{j_k}, \hat{G}_{(k)}\}.
\]

**Step 5.** From Proposition 11 and the fact that \( j_k \) is the deactivated arm (i.e., \( j_k = \arg\max_{i \in K_k} \hat{G}_i \)) we have
\[
(1 - c_2)G_{(k)} \leq \hat{G}_{a_k} \leq \hat{G}_{j_k} \leq G_{j_k} + c_2 \max\{G_{j_k}, \hat{G}_{(k)}\}.
\]
We conclude by considering the two possible cases for the max term.

**Case 1** \( G_{j_k} > G_{(k)} \)

We have \( (1 - c_2)G_{(k)} \leq G_{j_k} + c_2 G_{j_k} \). Since \( \frac{1 - c_2}{1 + c_2} \geq 1 - 2c_2 \), we get
\[
G_{j_k} \geq \frac{1 - c_2}{1 + c_2} G_{(k)} \geq (1 - 2c_2)G_{(k)}.
\]

**Case 2** \( G_{j_k} \leq G_{(k)} \)

Here we have \( (1 - c_2)G_{(k)} \leq G_{j_k} + c_2 G_{(k)} \), whence
\[
(1 - 2c_2)G_{(k)} \leq G_{j_k},
\]
which concludes the proof. \( \square \)
with the results of the previous sections, the proof of Theorem 1 is immediate. First, assume that event $\xi$ holds. Note that properties (i) and (ii) of the induction assumption hold for phase $k = 1$. Lemmas 5 and 6 prove the induction step, showing that properties (i) and (ii) hold for all phases $k$. It remains to consider the error probability for event $\xi$. This is handled by Lemma 4, where we finally choose $c_1 = 1/8$, $c_2 = 1/4$ so that $0 < c_1 < 1$, $0 < c_2 < 1/2$ and $c_2 \geq \frac{c_1}{1-2c_2}$. \hfill \Box

## H Fixed Confidence Results: Proof of Theorem 2

We first introduce a high-probability event corresponding to the confidence bounds used by our algorithm.

**Lemma 7.** The event $\xi$ defined as

$$
\xi = \{\forall i \in K, \forall t > 0, |\hat{\mu}_i(t) - \mu_i| \leq \beta_i(t-1)\}
$$

holds with probability $1 - \delta$, where

$$
\hat{\mu}_i(t) = \frac{1}{T_i(t)} \sum_{t=1}^{T_i(t)} X_{i,t} \text{ and } \beta_i(t-1) = \sqrt{\log \frac{4Kt^2}{\delta}}.
$$

**Proof.** By Chernoff-Hoeffding’s inequality, the definition of the confidence intervals $\beta_i(t-1)$, and a union bound over all $T_i(t) \in \{0, \ldots, t\}$, $t = 1, \ldots, \infty$. \hfill \Box

Recall that

$$
U_t' = \{U : \forall V \in C, \hat{\Delta}_{U,V}^+(t) > -\delta_{U,V} \max_{W \in C} \hat{G}_{W,U}^+(t)/2\}
$$

and

$$
\hat{G}(t) = \max_{U \in U_t', V \in C} \hat{G}_{V,U}^+(t) \text{ and } (U_t, V_t) = \arg\max_{U \in U_t', V \in C, U \neq V} \hat{G}_{V,U}^+(t).
$$

The following lemma gives a lower bound on $\hat{G}(t)$.

**Lemma 8.** On the event $\xi$, for all time steps $t$, $\hat{G}(t) \geq \frac{1}{2}G_{I(t)}.$

**Proof.** First note that on event $\xi$, for any $t$ and any pair of decisions $U, V \in C$, we have $\hat{\Delta}_{U,V}^+(t) \geq \Delta_{U,V}$ and consequently $\hat{G}_{U,V}^+ \geq G_{U,V}$. The proof proceeds by distinguishing two main cases. We show the details for the case when $I(t) \notin U^*$. The case $I(t) \in U^*$ can be dealt with using similar arguments.

**Case 1** $I(t) \in U_t$

We introduce $W_t = C_{U_t}$, which exists since $U_t \neq U^*$, as $I(t) \notin U^*$ and $I(t) \in U_t$. We have

$$
\hat{G}(t) = \max_{U \in U_t', V \in C} \hat{G}_{V,U}^+(t) \geq \hat{G}_{W_t,U}^+(t) \geq \frac{\hat{\Delta}_{W_t,U}^+(t)}{d_{U_t,W_t}} \geq \frac{\Delta_{W_t,U}^+(t)}{d_{U_t,W_t}} \geq \min_{U \in C, U \neq W_t} \frac{\Delta_{U,U}^-(t)}{d_{U,U}} \geq G_{I(t)},
$$

where (a) follows from the fact that $W_t = C_{U_t}$ and $I(t) \in U_t$, and (b) is due to $I(t) \notin U^*$ so that its complexity is defined as the minimum over decisions $U$ to which it belongs.

**Case 2** $I(t) \in V_t$

Let $W_t = C_{V_t}$, noting that $W_t$ is well-defined since $V_t \neq U^*$, as $I(t) \notin U^*$ and $I(t) \in V_t$.

**Case 2.1** $V_t \in U_t'$: Similar to Case 1, we have

$$
\hat{G}(t) = \max_{U \in U_t', V \in C} \hat{G}_{V,U}^+(t) \geq \hat{G}_{W_t,V}^+(t) \geq \frac{\hat{\Delta}_{W_t,V}^+(t)}{d_{V_t,W_t}} \geq \min_{U \in C, U \neq W_t} \frac{\Delta_{U,U}^-(t)}{d_{U,U}} \geq G_{I(t)},
$$

where (a) follows from the fact that $W_t = C_{U_t}$ and $I(t) \in U_t$, and (b) is due to $I(t) \notin U^*$ so that its complexity is defined as the minimum over decisions $U$ to which it belongs.
where (a) holds by $V_i \in \mathcal{U}_i'$ and the definition of $\hat{G}^+(t)$, (b) follows from $W_t = C_{V_i}$ and our assumption $I(t) \in V_i$, and (c) is due to $I(t) \notin U^*$ so that its complexity is defined as the minimum over decisions $U$ to which it belongs.

**Case 2.2** $V_i \notin \mathcal{U}_i'$: In this case, by definition of $\mathcal{U}_i(t)$ there exists a decision set $Z_i$ such that $\hat{G}^+_{V_i,Z_i}(t) \leq -\frac{1}{2} \max_{W \in \mathcal{C}} \hat{G}^+_{W,V_i}(t)$. Therefore, we have

$$\hat{G}^+_{V_i,Z_i}(t) \leq -\frac{1}{2} \max_{W \in \mathcal{C}} \hat{G}^+_{W,V_i}(t) \leq -\frac{1}{2} \hat{G}^+_{W_i,V_i}(t) \overset{\text{(37)}}{=} -\frac{1}{2} G_{W_i,V_i} \leq -\frac{1}{2} G_{I(t)},$$

where the last equality follows from the fact that $I(t) \notin U^*$ and the definition of $G_{I(t)}$ in that case. We now focus on the three decision sets $V_i, U_i, Z_i$ and define the value $\hat{\mu}_i$ associated to arms $i \in V_i \cup U_i \cup Z_i$ as

$$\hat{\mu}_i =\begin{cases} \hat{\mu}_i^-(t) & \text{if } i \in U_i, \\ \hat{\mu}_i^+(t) & \text{if } i \in (V_i \cup Z_i) \setminus U_i. \end{cases}$$

We also define $\hat{G}^+_{Z_i,V_i}, \hat{G}^+_{V_i,U_i}, \hat{G}^+_{Z_i,V_i}$ as well as $\Delta_{Z_i,U_i}, \Delta_{V_i,U_i}, \Delta_{Z_i,V_i}$ obtained by using $\hat{\mu}_i$ instead of $\mu_i$ in their computation. Then get

$$\Delta_{Z_i,V_i}(t) = \sum_{i \in Z_i \setminus V_i} \hat{\mu}_i \geq \sum_{i \in V_i \setminus Z_i} \mu_i - \sum_{i \in (Z_i \setminus V_i) \cap U_i} \mu_i = \sum_{i \in (Z_i \setminus V_i) \cap U_i} \hat{\mu}_i^+(t) + \sum_{i \in (V_i \setminus Z_i) \cap U_i} \hat{\mu}_i^-(t) \geq \sum_{i \in (V_i \setminus Z_i) \cap U_i} \hat{\mu}_i^+(t) - \sum_{i \in (Z_i \setminus V_i) \cap U_i} \hat{\mu}_i^+(t) = \Delta_{Z_i,V_i}^+(t).$$

Furthermore,

$$\hat{G}^+_{Z_i,U_i}(t) \overset{(a)}{=} \hat{G}^+_{Z_i,U_i} \overset{(b)}{=} \min \left( \hat{G}^+_{Z_i,V_i}, \hat{G}^+_{V_i,U_i} \right) \overset{(c)}{=} \min \left( \hat{G}^+_i, \hat{G}^+_{V_i,U_i} \right) \overset{(d)}{=} \min \left( -\hat{G}^+_{V_i,Z_i}(t), \hat{G}^+_{V_i,U_i} \right) \overset{(e)}{=} \min \left( 1/2 \hat{G}^+_{I(t)}, \hat{G}^+_{V_i,U_i} \right),$$

where (a) and (c) are obtained by the definition $\hat{G}$, (b) follows from $\hat{\mu}_U < \hat{\mu}_V < \hat{\mu}_{Z_i}$, and an analogue of Proposition 3 with strict inequality in case of $\hat{G}^+_{V_i,U_i} \neq \hat{G}^+_{Z_i,V_i}$, (d) uses equation 39, and (e) is by equation 37.

Now let us assume $\hat{G}^+(t) = \hat{G}^+_{V_i,U_i}(t) < 1/2 \hat{G}^+_{I(t)}$, from which we will derive a contradiction. From equation 37 and by definition of $\hat{G}$, we have $\hat{G}^+(t) = \hat{G}^+_{V_i,U_i}(t) < 1/2 \hat{G}^+_{I(t)} \leq \hat{G}^+_{Z_i,V_i}$, so we have strict inequality in (b) of equation 40. Consequently, we can derive from 40 the contradiction

$$\hat{G}^+_{Z_i,U_i}(t) > \min \left( \hat{G}^+_{V_i,U_i}(t), 1/2 \hat{G}^+_{I(t)} \right) \geq \hat{G}^+_{V_i,U_i}(t) = \max_{V \in \mathcal{C}} \hat{G}^+_{V_i,U_i}(t),$$

which completes the proof of $\hat{G}^+(t) \geq 1/2 \hat{G}^+_{I(t)}$. $\square$

The following Lemma shows that any set $U$ in $\mathcal{U}_i$ also is in $\mathcal{U}_i'$. 

---

**Improved Learning Complexity in Combinatorial Pure Exploration Bandits**

**Lemma**

The following Lemma shows that any set $U$ in $\mathcal{U}_i$ also is in $\mathcal{U}_i'$. 

---

**Proof**

By definition of $\mathcal{U}_i'$, we have $\mathcal{U}_i' \subset \mathcal{U}_i$. Therefore, if $U \in \mathcal{U}_i$, then $U \in \mathcal{U}_i'$.

$\square$

---

**Corollary**

The following Corollary shows that any set $U$ in $\mathcal{U}_i$ also is in $\mathcal{U}_i'$. 

---

**Proof**

By definition of $\mathcal{U}_i'$, we have $\mathcal{U}_i' \subset \mathcal{U}_i$. Therefore, if $U \in \mathcal{U}_i$, then $U \in \mathcal{U}_i'$.

$\square$
Lemma 9. On the event \( \xi \), for all time steps \( t, U_i \subset U'_i \).

Proof. It is obviously sufficient to show that the threshold \(-T_{U,V}(t)\) \( \leq 0 \). On the event \( \xi \), we have \( \max_{W \in C} \hat{G}_{W,U}^+(t) \geq \hat{G}_{U,V}^+(t) \geq G_{U,V}^+ \geq 0 \). By definition of \( T_{U,V}(t) \), this implies that \(-T_{U,V}(t)\) \( \leq 0 \). \( \square \)

The following Lemma gives an upper bound on \( \hat{G}^+(t) \).

Lemma 10. Assume that event \( \xi \) holds. Then \( 8\beta_{I(t)}(t-1) \geq \hat{G}^+(t) \) for all \( t \).

Proof. First note that

\[
\hat{G}^+_{V_i,U_i}(t) \overset{(a)}{=} \frac{1}{2} \max_{W \in C} \hat{G}_{W,U}^+(t) \overset{(b)}{=} -\frac{1}{2} \hat{G}^+_{V_i,U_i}(t),
\]

where (a) follows from \( U_i \in U'_i \) and the definition of \( U'_i \) and (b) from the definition of \( U_i \) and \( V_i \). Moreover, we have

\[
\hat{G}^+_{V_i,U_i}(t) \overset{(a)}{=} \frac{2}{d_{U_i,V_i}} \sum_{i \in U_i \cap V_i} \beta_i(t-1) - \hat{G}^+_{U_i,V_i}(t) \leq \frac{2}{d_{U_i,V_i}} \sum_{i \in U_i \cap V_i} \beta_i(t-1) + \frac{1}{2} \hat{G}^+_{V_i,U_i}(t),
\]

where (a) because \( \hat{G}^+_{U_i,V_i}(t) + \hat{G}^+_{V_i,U_i}(t) = 2 \sum_{i \in U_i \cap V_i} \beta_i(t-1) \), and (b) is because of equation (43). Hence, we obtain

\[
\hat{G}^+(t) = \hat{G}^+_{V_i,U_i}(t) \leq \frac{4}{d_{U_i,V_i}} \sum_{i \in U_i \cap V_i} \beta_i(t-1). \tag{44}
\]

Moreover, as we will demonstrate in the following, we have

\[
\frac{1}{d_{U_i,V_i}} \sum_{i \in U_i \cap V_i} \beta_i(t-1) \leq 2\beta_{I(t)}(t-1). \tag{45}
\]

We show this in detail for the case when \( I(t) \in U_i \), the case \( I(t) \in V_i \) is similar. For \( I(t) \in U_i \), we have \( \sum_{i \in U_i \cap V_i} \beta_i(t-1) \geq \sum_{i \in V_i \setminus U_i} \beta_i(t-1) \) and consequently,

\[
\sum_{i \in U_i \cap V_i} \beta_i(t-1) = \sum_{i \in U_i \cap V_i} \beta_i(t-1) + \sum_{i \in V_i \setminus U_i} \beta_i(t-1) \leq 2 \sum_{i \in V_i \setminus U_i} \beta_i(t-1).
\]

Since for \( I(t) \in U_i \), we have for all \( i \in U_i \setminus V_i \) that \( \beta_i(t-1) \leq \beta_{I(t)}(t-1) \), we therefore obtain

\[
\sum_{i \in U_i \cap V_i} \beta_i(t-1) \leq 2 \sum_{i \in U_i \setminus V_i} \beta_i(t-1) \leq 2d_{U_i,V_i} \beta_{I(t)}(t-1)
\]

and consequently,

\[
\frac{1}{d_{U_i,V_i}} \sum_{i \in U_i \cap V_i} \beta_i(t-1) \leq 2 \frac{d_{U_i,V_i}}{d_{U_i,V_i}} \beta_{I(t)}(t-1) \leq 2\beta_{I(t)}(t-1),
\]

which proves equation (45). Finally, combining (44) and (45) gives the claim of the lemma. \( \square \)

Finally, we are ready to give the proof of Theorem 2.
Proof of Theorem 2. First note that by Lemma 9 on event $\xi$ we have $\mathcal{U}_t \subseteq \mathcal{U}'_t$, so the algorithm is well-defined, since as long as $|\mathcal{U}_t| > 1$ also $|\mathcal{U}'_t| > 1$ and there is always an arm to be pulled.

Next, we show that with probability of at least $1 - \delta$, the algorithm returns the optimal set $\mathcal{U}^*$. Indeed, assume that $\xi$ holds and that $\mathcal{U}^*$ is rejected from $\mathcal{U}_t$ at some step $t$. Then there exists a set $V$ such that $0 \geq \hat{\Delta}_{\mathcal{U}^*,V}^+(t) = \mu_{\mathcal{U}^*,V}(t) - \mu_{\mathcal{V}^*}(t) \geq \mu_{\mathcal{U}^*} - \mu_{\mathcal{V}} > 0$, which is a contradiction. Hence, the claim follows from Lemma 7.

Finally, let us consider the sample complexity of our algorithm. By Lemma 10 and Lemma 8 we have for any pulled arm $i$ that $8\beta_i(t) \geq \tilde{G}^+(t) \geq \frac{1}{2} G_i$. Summing over all arms $i \in K$, this gives for each $t$ that $T_i(t) \leq 128 H_i \log(4Kt^2/\delta)$. Therefore,

$$\sum_{i \in K} T_i(t) = t \leq \sum_{i \in K} 128H_i \log(4Kt^2/\delta) \leq 128H \log(4Kt^2/\delta).$$

Thus, as soon as $t$ reaches $t \geq 128H \log(4Kt^2/\delta)$, the algorithm stops. Denoting this step by $\tilde{n}$ and using Lemma 8 of [Antos et al., 2010] in order to solve this equation gives $\tilde{n} \leq O(H \log(HK/\delta))$. \qed
